METALLURGICAL AND CHEMICAL ENGINEERING

A Monthly Journal being the Incorporation of
Electrochemical and Metallurgical Industry
and Iron and Steel Magazine.

VOLUME XI

From January to December 1913

436836
3. 7. 45

NEW YORK:
McGRAW PUBLISHING CO.

INDEX TO VOLUME XI

GENERAL ALPHABETICAL INDEX

Entries from the Synopsis of Periodical Literature are indicated by S. (Synopsis); from the Analysis of Current Electrochemical, Chemical and Metallurgical United States Patents by P. (Patents); from the Digest of Electrochemical United States Patents Prior to July, 1902, by D. (Digest).

A

ABBE, Paul O.	596	ALLOYS: (Continued.)		American Institute of Metals.	540
Abbe, Carl O.	111	—Gun metal. Heat treatment. Primrose.	179	—Chicago Convention Report.	698
Abbe Engineering Co.	662	—Iron-nickel-copper. Clamer. (P.) ...	717	American Institute of Mining Engineers.	602
Abrasive. Aluminous. Blouin. (P.) ...	56	—Lead-copper-iron. (P.) ...	717	—Annual meeting.	149
Abrasive Age.	256	—Manganese-titanium-silicon. Becket.	438	—Iron and Steel Committee.	354
Absorption of hydrochloric acid. Meyer.	458	—Micrometry. Mathewson.	619	—Montana meeting.	521
Absorption towers. Heinze.	359	—Jeffries.	608	American Iron and Steel Institute.	601
Accidents. Carrying the injured in.	434	—Non-ferrous. Nomenclature. Burgess.	609	American Melting Co.	660
Acheson, E. G.	70	—Osmium-platinum. Zimmermann.	590	American Metal Co.	244
Acids:		—Silicon-titanium. Girod.	8	American Mining Congress.	68, 123, 541
—Absorption and reaction towers. Heine.	359	—Sodium. Rossiter. (P.) ...	717	American Museum of Safety.	70
—Hydrochloric. Absorption. Meyer.	458	—Sodium. volume and constitution. Givertier.	648	American Smelting & Refining Co.	237
—Hydrochloric. and Boron. Hayden.	658	—Volume changes. Chamberlain.	568	American Transformer Co.	662
—Nitric. in England.	714	—White metals. Electroanalysis. Fairchild.	381	American Zinc Ore Separating Co.	571
—used in pickling. Storey.	45	—Zinc alloy. Malleable. Bayliss. (P.) ...	717	Ammeter and voltmeter. Keystone.	555
—Acid-proofing floors of battery rooms.	56	(See also Brass and Ferroalloys.)		AMMONIA:	
Acmeite valve.	659	ALUMINA:		—for making nitric acid. Ostwald.	476
Addicks, Lawrence. Portrait.	619	—from clay by fluoride process. Childs.	231	—from calcium cyanamide.	438, 476
Agitation froth process. (S.) ...	53	—from mineral silicates. Cowles.	140	—Haber synthetic ammonia process.	173
Agitator for ore slime. Trent. (P.) ...	656	Serpuk process. Richards.	137, 281	—Synthetic. Haber and Le Rossignol.	211
Agitator for ore slime. Warwick. (P.) ...	292	—Tucker.	139	—Vapor saturated and superheated.	661
Agitator. Slime. Wright-Janetsch. (S.) ...	619	—Solubility in fused fluorides. Doremus.	121	Ammonium compounds. Production.	462
Agitator test in cyanide practice.	112	—Cowles.	178	—Steinmetz. (P.) ...	462
Agitator. (See also Cyanide process.)		—Uses as abrasive and refractory.	179	"Amphidizing" copper ores. Bradley.	716
Air lift pump. Davis and Weidner.	129	Saunders.	143	(P.) ...	218
Air lift versus centrifugal pumps. Rhodes.	162	—Blouin. (P.) ...	56	Anaconda Butte Electric Railway.	420
Air lift for sludge pumping.	118	ALUMINUM:		Anaconda Copper Mining Co.	372
Air lift for pumping in California cyanide work.	640	—Alloy. McAdams. (P.) ...	658	Anaconda. Slime concentration. Hayden.	538
Air. Preheating. Hamilton and Johnson.	654	—Alloy with copper. Gleason. (P.) ...	717	Anaconda. Slime handling.	536
Alkali. Available in Lime.	693	—Alloys with copper. Influence of phosphorus. Read.	568	ANALYSIS:	
Alaska. Metal production.	693	—as deoxidizer.	231	—Aluminum in ferrovanadium. Clark.	91
Alkali carbide.	693	—Manufacture in Europe.	632	—Arsenic and antimony in copper.	521
Alkali hydroxides and carbonates. Formulae for calculation. Mereness.	476	—nitride. Serpek process.	137, 139, 281	—Brownson.	164
ALLOY:		—solder. Siefert.	197	—Copper and lead simultaneously determined with rotating anode.	590
—Aluminum. McAdams. (P.) ...	658	Aluminum Industry Co.	398	—White.	164
—Atom-per cent and weight-per cent diagram.	365	Aluminous abrasive. Blouin. (P.) ...	56	—Cyanide solutions. Wilmoth. (S.) ...	164
—Boron-titanium. Weber.	92	AMALGAMATION:		—Electrolytic of copper alloys. Fairchild.	380
—Brass. Addicks. (P.) ...	55	—Effect of heat.	98	—Flue gas. Burrell and Seibert.	251
—Cadmium-chromium for cutting tools.	291	—Electrolytic barrel. Porter. (P.) ...	60	—Gas. Modification of Jaeger method. Worrell.	245
—Copper. Schmid. (P.) ...	55	—in electric cyaniding. Tatno and Dehus. (P.) ...	60	—Gold and iridium in black sand. (S.) ...	652
—Copper. Electroanalysis. Fairchild.	380	Molz. (D.) ...	116	—Gold ore. Lass. (S.) ...	164
—Copper. Hard alloy. Nolan. (P.) ...	610	Badger. (D.) ...	60	—Gold, silver and platinum. Trenkner.	567
—Copper. Melting points. Gillett and Norton.	717	American Cement Directory.	170	—Lead in cyanide. (S.) ...	53
—Copper. Manganese. Gleason. (P.) ...	517	American Chemical Society.	136, 540, 607	—Oxygen in copper and brass. West.	558
—Influence of phosphorus. Read.	717	—Rochester meeting.	433	—Oxygen in iron and steel. McMillen.	86, 176
—Copper-titanium. Ladoll. (P.) ...	55	American Electrochemical Society.	535	—Cushman.	176
—Effect of rapid cooling on constitution. Gulliver.	180	—Atlantic City meeting Report.	277	—Phosphorus in steel.	715
—for metal tape. McConnell. (P.) ...	717	—Colorado Meeting Report.	569	—Phosphorus in vanadium steels. Hagmaier.	28
—German silver. Microstructure. Hudson.	179	—Pike's Peak session.	570	—Spectrum analysis. Quantitative.	633
		—Denver session.	571	—Shank.	494, 552
		—Golden session.	581	—Sulphur in ferrovanadium. Clark.	256
		—Boulder session.	577	—Vanadium in ferrovanadium. Clark.	195
		—New York Session.	137, 539, 607, 619	—Zinc-dust precipitate. Laying. (S.) ...	165
		American Foundrymen's Convention.	608	Annealing furnace. Stadler.	170
		American Inst. Chemical Engrs.	310, 540	Annealing muffle. Wall.	215
		—Boston meeting.	430	Anglo-American Exposition.	458
		—Code of Ethics. Thompson.	9	Annual Tables of Constants.	110
		—Patent reform.	10		

Anodes. Lead peroxide and manganese peroxide.....	44
Anodic retardation phenomena. Grube.....	680
Anthracite coal. Manufacture and use as fuel. Johnson.....	692
Antimony from ores. Wet process. van der Ploeg, (D.).....	226
U. S. production.....	708
Apoporometer. Joly.....	1067
Apprenticeship system for foundries. Alexander.....	608
Arizona Copper Co.....	238, 449,
Asano, Kosaker.....	115,
Assay Office of New York.....	301
Assay. Vanning for tin.....	63
Assaying ore containing coarse gold. (P.)	349
Association of American Steel Manufacturers. Open-hearth specifications.....	88
Atlantic City Meeting of the Am. Elec. Society.....	70
Atmospheric impurities. Investigating and recording. Kershaw.....	339
Atmospheric pollution. Measurement. Kershaw.....	615
Atomism versus Continuity. Lodge.....	545
Atom percent.....	365
Atwater, M. W.....	179,
Austin, E. A.....	225

B

BACHARACH, Herman.....	225
Badger Chemical Diary.....	170
Badgley, Chas. W.....	225
Bakeland, Willard Gibbs Medal.....	209
Bakelite billiard balls.....	19
Bakelite. Constitution.....	312
Bakelite patent recognition.....	361
Balaklava smelter.....	606
Bannister, Chas. O.....	263
Barium sulphate.....	306
Base bullion. Refining. Cassel, (D.)	369
Battery. Edison-Lalande. Test. Sanford.....	129
Edison storage. Bennett and Gilbert	281
Leclanche. (P.).....	719
Reck, Richard.....	480,
Benjamin, Geo. H.....	225
Benzeno, Electrolytic chlorination. Van Name and Maryott, (S.).....	165
Bessemer steel industry. Can it be saved?.....	119
Billard Hardware Co.....	82
Billiard balls of bakelite.....	19
Bitlitter alkali-chlorine cells.....	79
Bismarck Consolidated Mill. Cyanide practice.....	531
Bisulphide process. (S.).....	573
Black Hills. Influence in transportation.	431
Black sand and floating minerals. Recovery. Neill, (S.).....	417
Black sand and gravel. Jigging.....	477
Black sand. Assay of gold and iridium. (S.).....	652
Blackwater Mines. Reduction works.....	241
BLAST FURNACE:	
Air-cooled. Stevens, (P.).....	655
Burden.....	666
Charging apparatus. Windsor-Richards and Lewis, (P.).....	344
Construction. J. E. Johnson.....	412
Dry blast. Ehrenwerth.....	412
Gayley.....	147
Howe.....	147
Gas purification. Field washer. Herwegh and Wagner.....	390
Heat loss by radiation.....	702
Iron blast furnace and its fuels. Johnson.....	687
Operation. Mathesius.....	699
Bogue, Charles.....	204
Boiling of metals. Richards.....	596
Bone, A. J.....	596
BOOK REVIEWS:	
Allman, A. J. The principles of applied electrochemistry.....	61
Barclay, Wm. R., & Harnsworth, Cecil H. Electroplating.....	226
Bengough, Guy D., & Hudson, O. F. Iron and steel.....	598
Biedermann, Rudolph. Chemiker-Kalendar, 1913.....	366
Bigelow, S. Lawrence. Theoretical and physical chemistry.....	61
Bolton, R. P. An expensive experiment.....	303
Brunswick, H. Explosives.....	366
Carnegie, T. L. High speed steel.....	664
Centenary celebration of the First Commercial Gas Company.....	62
Charlton, W. H. American mine accounting.....	472
Coste, I. H. The calorific power of gas.....	365
Cross, Wm. E. Investigations of methods of analyses of cone products.....	473
Deiser, Geo. F. Law of electrolysis. Uses of electricity and electrolysis.....	726
Desch, Cecil H. Metallurgy.....	424
Doelter, C. Handbuch der mineralchemie.....	424
Field, Samuel. The Principles of electro-deposition.....	366

BOOK REVIEWS. (Continued.)	
—Giolliti, Federico La Cementazione dell' Acciaio.....	62
—Goadby, Kenneth W., and Legge, Thos. H. Lead poisoning and lead absorption.....	62
—Gulliver, S. H. Metallic alloys, their structure and constitution.....	472
—Guthrie, A. W., and Tolman, Wm. H. Hygiene for the worker.....	62
—Hainsworth, Cecil H., and Barclay, Wm. R. Electroplating.....	226
—Harvard, F. T. Refractories and refractory work.....	226
—Hinrichsen, F. W. Das material-prüfungswesen.....	395
—Hoffman, Fritz. Atomprozente und Gewichtszusammensetzung.....	726
—Hofmann, H. O. General Metallurgy.....	598
—Hudson, O. F., and Bengough, Guy D. Iron and steel.....	598

C

C. & C. ELECTRIC & Mfg. Co.....	467
Caetani, Gelasio.....	115,
Calcium cyanamide for making ammonia and nitric acid.....	438,
Calvo, Pedro.....	423
Cam & Motor Mill. Rhodes, (S.).....	591
Campbell, A. R.....	115
Canada. Mineral production.....	276
Captains of industry. Chemists.....	63
CARBON:	
—Bricks. Manufacture.....	82
—electrodes for electrolytic cells. Har den.....	242
—Electrodes. (See also Furnace, Electric Electrodes.....	619
—Metallography. Roush.....	619
—monoxide. Detection and estimation. Levey and Tecoul.....	158
—Gnase.....	158
—Purifying for filaments. Billiter, (P.)	462
—Resistance and temperature. Northrup.....	275
Carbonates, alkali, and hydroxides. Formulas for calculation. Mereness.....	476
Carborundum. Outcome of patent suit. 203.	676
Carborundum refractories. Tene.....	484
Carborundum Company.....	256
Carborundum Company. Silicon castings.	102
Carlyle, Wm. A.....	301
Carnegie Institute of Technology.....	407
Carnotite industry. Fischer.....	583
Carrier, F.....	662
Carroll, Wm. F.....	92
Car Wheels, Chilled iron. Weber.....	92
Case, A. H.....	103
Castings of iron for chemical industries.	103
Castner-Kellner Alkali Co.....	14
Castner-Kellner Alkali Works.....	44
Catholic Retardation Phenomena. Grube	680
Casin, Franz.....	282
Cells. Concentration. See type. Bentner	282
Cells. (See also Batteries.)	
Cement. Action of alkali and sea water.	442
—Bates, Phillips & Wig.....	167
Cement. Portland.....	88
Cement floor.....	88
Centrifugals. Design, construction and uses. Stephens.....	358
Centrifugal. Oil extracting and washing. D'Olier.....	295
Centrifugal. Self-balancing. Tolburst.....	297
Centrifugal pumps. De Huff.....	469
Centrifugal separator machines. Griscom.....	423
Chamber of Mines of Western Australia	233
Chance, Edwin M.....	423
Channing, J. Parker.....	225
Charcoal as furnace fuel. Johnson.....	692
Charcoal. Manufacture. Johnson.....	690
Chauvenet, Regis.....	423
Champion Rect.....	183
Champion Engineering.....	307
Chemists as captains of industry.....	63
Chemists' Club Library.....	70
Chesapeake Pulp & Paper Co.....	458
Chicago Pneumatic Tool Co.....	458
Chilean Mills. Size of feed.....	146
Chino Copper Co.....	238
CHLORINATION:	
—Base metals in Utah.....	605
—Dry of mixed sulphide ores. Matheson, (P.).....	159
—Electric. Long, (D.).....	60
—Wright, (D.).....	60
—of benzine by electrolysis. Van Name and Maryott, (S.).....	165
—Roasting. Christensen, (P.).....	657
Chlorine-alkali cells of Billiter. Allmand	119
Chlorine from sodium. Cambron and Moore, (P.).....	213
Chromium-cobalt alloys for cutting tools. Haynes, (P.).....	208
Chromium concentrates. Electric smelting. Lyon and Keeney.....	579
Chromium ores. Electric smelting. Keeney.....	585
Cia Fundidora de Hierro y Acero.....	92
Clark & Sharrow.....	82

- Classification. Need of better. Richards. (S.) 654
- Classifiers. Anaconda. Ammon. 528
- well 528
- Richards pulsator 210
- Sand-slime. Argall. (P.) 159
- Clerk, F. L. 115
- Cleveland Brass & Metal Co. 228
- Cloth, Filter. Cleaning 228
- Clyde ship building. 104
- COAL:
- Cleaning by electrostatic process. MacGregor 581
- Dust explosions 650
- Government specifications for purchase 293
- Oxidation and process of combustion. Porter 543
- Pulverized, as fuel. Barnhurst. 127, 721
- Raymond 108
- Power 170
- "Raw" coal as furnace fuel. 693
- Tar. Anticorrosive properties. 650
- Colalt. Electrolizing. Reed. (P.) 348
- Colalt. Electrolizing. Watts. 384
- Colalt. Chromium alloy for cutting tools. Haynes. (P.) 293
- Code of ethics. American Institute of Chemical Engineers. Thompson. 9
- Cohesion. In the crystalline of Metals. Rosenheim and Ewen. 656
- Coincidences of meetings. 580
- COKE:
- as furnace fuel. Johnson. 690
- from coal. Increased yield. 446
- Manufacture. Johnson. 698

The Electrochemical Publishing Company, publisher of this journal, was formed ten years ago with the co-operation and support of the McGraw Publishing Company. All of the stock of the Electrochemical Publishing Company has now been acquired by the McGraw Publishing Company, which will, hereafter, be the publisher of METALLURGICAL AND CHEMICAL ENGINEERING. The stockholders of the Electrochemical Publishing Company have become stockholders of the McGraw Publishing Company. There will be no change in the editorial and business staff, or in the management, except that the staff will be able to call more freely than ever upon the professional and business resources of the McGraw Publishing Company.

I sincerely hope that this step, which was taken with the hearty and unanimous consent of the minority stockholders of the Electrochemical Publishing Company, will enable this journal to fulfill in future still more energetically its mission in technical journalism and to remain true to the ideals for which it has stood these ten years. To this end I pledge my full support.

JAMES H. MCGRAW.

General Business Conditions and the Metal Markets in 1912.

The expansion in the metal markets in the past year has exceeded the expectations of many and the hopes of a few. For, considered as far as output and prices go, 1912 has been a banner year in the metallurgical industry. Indeed, in the past two months it has been pushed to the extreme in making prompt deliveries in certain lines. As the metal markets are such a sure index of the growth of the business of the United States, in considering the past general aspects of the metal business, due regard must be paid to those fundamental commercial prime-movers, the crops and the psychological atmosphere. So, it must be clearly held in mind that all crops save cotton were in 1911 considerably below the average and that in 1912 all the crops were considerably above the average. In the ultimate analysis, the price of foodstuffs is the chief immediate factor in industrial life. It can be laid down as a fact, therefore, that the balting tendency manifest a year ago had its main cause in the poor condition of agriculture, and that the rush of business in the latter part of 1912 was due to the assurance that the farmer had been bountifully aided by Dame Nature and that there was a surplus of food products. This in point of fact counteracted the effects of the presidential campaign.

At the same time man cannot live by bread alone, and the profound influence of what people think and feel preponderates over the direct acting stomachic forces—potent as they are in their own sphere. The general mental and spiritual food that was consumed in America contained certain good elements and certain poisonous elements. Yellow journals and several of the magazines generate in one

a feeling of horror and disgust. Yet there are many millions of calm, sensible and sober men and women who form the real opinions of society and on whose mental balance and on whose self-control our entire national welfare and life depends. These people are the substance of America. The others are the excrescences. Now, life is derived from sentient intelligence and from real sources of subjective power.

With these conceptions in mind, let us turn to specific events of the past year. At first there was a braking effect on the wheels of industry because of the poor crops of 1911, and due to the usual apprehension of a presidential year. However, copper and spelter started to move fast and strong in the early spring. The great expansion in the electrical trade resulted in an enormous consumption of copper and as we have said before there cannot long be in this age of electricity too much copper.

For a considerable period in recent years, business has been dominated by a spirit of rational conservatism. This spirit has shown faith in the future and practically has exercised energy in present endeavor. Without this we would now be in a perilous condition. Since there was a good foundation of conservatism, when once the good crops of 1912 were harvested, something that approached a boom arose. The election over, a scarcity of labor and supplies was marked. At the same time the Balkan war came on and caused a general restriction of credit in Europe. Now, slowly and surely, the inhibiting forces manifest themselves—in traces only, to be sure, but certainly in a slight tendency to quiet. Labor and political troubles, phenomena closely connected with all industrial life, were manifest throughout the year. The fear of them is an inhibiting force. All such forces are much needed checks on extravagance and the actions of the unintelligent. An individual case now is the query of the business man, "Why should I build now when labor and capital and supplies are scarce, high, and dear?" No observer can deny that this is the case and no reasoning person can refuse to admit that a negative answer is the logical one.

Another inhibiting force is that large sums of money have been sunk in enterprises of sure merit, such as the Panama canal, whose return to capital must needs be long delayed. This state of affairs is not so pronounced as in 1905-7, but it is nevertheless a check to expansion. It would seem inevitable and natural to expect for several reasons soon a holding off in the demand for metals and a market much more favorable to the consumer. A feeling of uncertainty begets caution, for the emotion of doubt in an intelligent person becomes volitional caution.

Let us look at this phase broadly and consider the varying conditions of mental unrest that is so marked in the civilized world. Let us also remember the great ease and accuracy with which intelligence nowadays can be transmitted. From both it follows that we are to have short periods of expansion followed by equally short periods of retrenchment for the next few years as has been the case for the past five years. This is a healthy state of affairs, for it shows that moral forces are working quickly and surely in the industrial world.

Now the greatest fault with America is the widespread extravagance starting in with the so-called upper classes

that ought to know better but do not, and progressing thence by social migratory imitation to the working classes. This causes more trouble than all the wars, more than all vice, for it is fundamental in its perverse character. Fortunately or unfortunately, according to the viewpoint, this country is a young giant on whom excesses seem to make little effect. But the time has come for the country to put away childish things and to become a strong man under control.

This same extravagance engenders envy and is so the cause of political and social unrest. We can be sure that it makes for destruction, and, if it were not for the fact that it is not universal and that the great law of compensation acts against its increase, things would surely be pretty bad. Now, all the waste of extravagance prevents a larger healthy growth in the metal business.

Besides these far-reaching causes, there is, of course, the uncertainty that the coming tariff legislation brings. There seems to be a feeling that this country could profitably import some of its labor "in cans and boxes" and that the best way to stop labor troubles is by a gradual lowering of the tariff and that so immigration will be lessened and the nation will have time to absorb and assimilate the vast mass of immigrants already here so that we can reach a condition of social equilibrium. Moderate action in this way will be of great benefit, but any running amuck will distil over into business unrest.

After all has been said, however, we have certain facts to count on and to recite. The pig-iron production has reached the greatest annual total and the greatest daily average in its history. This is likewise true of steel. Prices of both have averaged fair.

Copper and spelter have made the greatest production as yet recorded and in the face of this prices have advanced. Lead has not made as satisfactory a showing. Apparently the copper business has not yet felt the incoming of several large producers. As the consumption both abroad and in this country has been enormous, it has been easy to keep copper prices at a good level. Whether this has been caused by the centralized control is, of course, a question. Undoubtedly the consumption has been so strong that such a process as that called "pegging" would have been easy. But, be that as it may be, 12.50 cents is altogether too low a price to be paid for the "red metal" if capital is to be attracted into the business at a rate needed for the demands of an electrical age. It is sure that new mines will not be developed unless the price of the metal is so high to make profits large enough to justify the risk. Still, all things considered, copper looks strong though much depends on European demand.

Spelter has likewise undergone an enormous expansion in the face of an increasing price. For the last six months spelter has averaged 7 cents per pound or over at New York, and has reached a price of 7.90 cents, thereby breaking all records. The zinc smelter has reaped a rich harvest, but as the prices of metal have been extremely high, prices for ore have been also high and the zinc mining companies have not suffered. Joplin, while still the most prominent ore center, does not hold the prominent place that it did formerly, and we have seen in 1912 Butte, the great copper district, becoming a producer of zinc ore on a large and serious scale.

For many reasons it can be concluded that there is present a spirit of caution both among producers and consumers of metal that is bound to check any decided increase of further expansion. But it can also be concluded that after this steadying influence has had its work, the fact that food-stuffs will be cheapened inevitably is bound to enlarge the purchasing power of the industrial classes. There will thus be a larger margin that can be spent otherwise and in the early spring we should see a stiffening of prices. There are born some good judges of metal markets, who believe that the latter tendency will be found to be so strong as to obliterate the evidences of the first. Later in the year, when the question of new crops comes up, there is another restricting factor that will come into play. So, eliminating the effect of chance events and allowing for the uncertainties of politics, the next year has a good outlook.

Last January we based our conservative views on the poor crops of 1911. Events have shown that our views were too conservative. This year our views may prove too optimistic. But, with much good feeling among sensible people of all classes and with the full dinner-pail that nature has provided the country, we reasonably expect that the metallurgical industry will receive the good treatment that it deserves for converting potential mineral wealth into the actual wealth of refined metals, which latter are modern civilization's prime requisites.

A Noteworthy Year in Iron and Steel.

The year which has passed into history was a most noteworthy one in the iron and steel industry, made so by commercial conditions as to demand which were not remarkable in themselves but which disclosed conditions in the industry deserving of special mention and in some respects of very careful thought.

There has been, as all know, a wonderful "revival" in the industry. This revival has not been produced by a spectacular increase in demand. In November, 1911, mills were making up rolling schedules, in many cases, from turn to turn, and were able to ship most products in from one day to one week after the receipt of specifications, while prices were dropping to their lowest point, as to finished steel since early in 1899 and as to pig iron since 1904. At the close of 1912 pig iron had advanced \$4 a ton and finished steel products an average of \$6.50 to \$7 per net ton, while the mills had actual specifications on books for three months of full operation, and contract business for from three to five months additional operation.

This was a wonderful reversal in the commercial position of the industry, yet the interesting fact is that in November, 1911, production was at a rate fully 75 per cent. as great as the rate in the three closing months of 1912. Consumption appears to have increased by one-third, which is not much, but there is reason to suspect that the consumption in ordinary channels has not really increased as much as that. In November, 1911, exports were at the rate of 2,250,000 tons per annum, and in the closing months of 1912 at the rate of 3,000,000 tons, an increase of 750,000 tons. Comparing the same periods there was an increase in the rate of iron and steel consumption by car shops of fully 1,000,000 tons per annum, and a considerable increase in the consumption of other railroad material. It seems fair to estimate that out-

side of the increases in exports and the increases in railroad consumption there has not been an increase in general demand of more than about 20 per cent at the outside. Of course, it must be recognized that the action of buyers in placing contracts far ahead, and in specifying material which cannot be delivered in less than three months is purely a result of the sold-up condition of the mills, and not a product of their own commercial position. In the condition in which these consumers found themselves in November, 1911, they would have contracted and specified just as far ahead had they observed a condition of the mills being behind in deliveries as they have been of late. Specifications accumulate when mills are slow in delivery and thus produce greater slowness until the movement plays itself out. That is the course in a free market, the roughly "unscientific," perhaps, but perfectly natural.

Much will be said in the current trade reviews of what caused this so-called wonderful revival in the iron and steel industry, and what further will come of it. With a free market, where what occurs is largely natural and inevitable, it avails little to discuss these points. Of much more interest, and of vastly more profit, is it to dwell upon the conditions in the alignment of the iron and steel industry which the developments of 1912 have disclosed.

First and foremost is the peculiar condition disclosed as to the supply of coke. We are familiar with lists of the beehive ovens of the country and statements as to the capacity of the by-product ovens. We have also seen compilations of the total blast furnace capacity of the country. Such compilations have a probable error which might be negligible when the compilation is used for some purposes, but which is altogether too great to make it worth while to devote time to a comparison of the relative capacities for coke-making and pig-iron production, equal to coke consumption. Far more conclusive is a study of commercial conditions, of market results, for there the conclusions are written in actual money, and "money talks."

From the low point, about January 1, 1912, pig iron in northern markets advanced an average of \$4 per ton. Contracts for Connellsville coke for the first half of 1912 were made in November, 1911, per net ton at ovens, at \$1.55 and \$1.60, and in December at \$1.05. At the close of 1912 the same coke was held, for the first half of 1913, at \$3.50, an advance equal to fully \$2 in the cost of making a ton of pig iron. Lake Superior iron ore was advanced, for the season of 1913 62 cents on Bessemer and 55 cents on non-Bessemer ores, equal to about \$1 in the cost of making pig iron.

The major operation is that of making pig iron, yet only one-fourth of the advance in pig iron stays with the blast furnace, which is an altogether unreasonable commercial movement. There are no coke ovens idle because there are not prospective customers for the coke, but there are many idle blast furnaces, with a pig-iron market awaiting them, and idle because they cannot secure coke at a suitable price.

The coke-making capacity of the Connellsville region is substantially the same as it was in 1906, six years ago. Meanwhile the blast-furnace capacity of the country has been increased almost one half, i.e. give each existing blast furnace the supply of raw materials and the market for pig iron, which existed in 1906, and about one-half more pig iron could be made. The commercial capacity is not

one-half greater, simply because the raw materials are not available, and market prices for pig iron are lower. Blast furnaces have been built in the past six years to the extent of about 9,000,000 tons annual pig-iron capacity, requiring 10,000,000 tons of coke and the coke supply has not been increased by anything like that amount.

Again, depending upon the market movement to disclose physical condition, one finds that billets and sheet bars have advanced \$10 per gross ton in this upward movement of about a year's duration, while the finished steel products made from them have advanced somewhat less than \$7 per net ton. A reasonable alignment would be that the finished product, the thing of greater value, should advance more per ton than the unfinished material. As outlined at some length in our current iron and steel market review, the condition arises largely from the fact that finishing capacity is usually in excess of steel-making capacity, through the expectation of builders that all branches of the finishing trade will not usually be fully employed throughout, the further fact that the transition from Bessemer to open-hearth steel has left Bessemer capacity unemployed when the attendant finishing capacity is equally available for rolling open-hearth steel, and finally the fact that there is a large demand for rails, while many of the billet and sheet bar mills are convertible into rail mills.

Obviously there is required a greater expansion in open-hearth steel-making capacity. The rate of new construction in this direction has been much less in the past two years than in immediately preceding years. Of the Bessemer capacity thrown idle by the change in demand towards open-hearth steel, there has been considerable utilization by adoption of the duplex process, but the developments in the building of pure open-hearth departments and the constitution of duplex departments has not been as rapid as the market movements show it should have been. That is, perhaps, not all of the story. The whole industry may be shaken any day by finding itself under the necessity of adopting a method of producing sound ingots, requiring little if any cropping. Comparison of steel ingot and rolled-steel production statistics show that there is being produced to-day in the steel works and steel rolling mills about 8,000,000 tons per annum of new steel scrap, practically all of which finds its way into open-hearth steel works, but a large part of which would suddenly disappear should a method of producing sound ingots be adopted. A large premium upon the non-scrap processes, like the duplex, would instantly be written, and those who had early adopted such processes could count themselves most fortunate.

This much for two clear facts which the movements in the year 1912 have disclosed, in that certain departments of the industry have not developed as they should. Perhaps it would be true to say that the whole industry has not grown as rapidly as it should have done. Five years ago—and the point is that many in the trade do not realize that it is as long as five years ago—men were saying that the industry was overgrown and that a period of years would be required for demand to grow up to capacity. For five years this demand has had a chance to grow. For two or three years following 1907, the year which saw that memorable slump in demand, capacity grew somewhat rapidly, but in the past two years it has grown but slowly. The country

is now making pig iron at the rate of only between 32,000,000 and 33,000,000 tons per annum, although apparently the existing capacity is strained, but in 1906 it actually produced 25,307,191 tons, and from the rate of growth which was shown by the increase from 1,205,663 tons in 1866 to 5,683,329 tons in 1886 and then to 25,307,191 tons in 1906, the tonnage for 1912 can be extrapolated as 40,000,000 tons, instead of the 29,600,000 tons estimated as the actual production of 1912 and the rate at the close of the year of only slightly more than 32,000,000 tons.

Metallurgy of Gold and Silver in 1912.

The past year was marked by many advances in the treatment of gold and silver ores. As might be expected, cyanidation held the premier place among processes, and strengthened its position as the prevalent method of gold recovery. No mention has been made of an attempt to revive chlorination, although one company in Utah is reported to have adopted a process in which a chloridizing roast is an important feature. Nothing of special importance has occurred in the way of electrolytic amalgamation, in spite of the fact that the records of the Patent Office indicate activity among inventors in this branch of metallurgy. It appears that there may be a legitimate field of operation for such processes, and we may look for tangible results from some of the proposals that have been made by competent engineers.

In the domain of amalgamation interest must center naturally in the radical departure at the Nipissin high-grade mill, in the Cobalt district, Ontario, Canada, where high-grade silver ore is given a combination treatment by amalgamation and cyanidation. Ore containing 2500 oz. silver per ton is ground to 20-mesh size and treated in a tube mill with 4 tons of mercury, 2 tons of 5 per cent cyanide solution, with a charge of 6 tons of pebbles. About 3 tons of ore is thus treated at once. The remarkable feature of the process is that over 95 per cent of the silver in the ore is recovered by amalgamation in the tube mill. The remainder is largely recovered from the cyanide solution.

From a business viewpoint, the most important event of the year in the cyanide industry was the decision of the U. S. Court of Appeals sustaining the validity and fundamental nature of the Moore vacuum filter patents. Vacuum filtration transformed the cyanide process as applied to slime, and contributed largely to the increase in gold production by cyanidation. It was natural that so important a process should be modified by other inventors, and equally natural that the originator should consistently defend his invention. To the victor belong the spoils, but we are of the opinion that a policy of moderation will be more effective than one of strict demand for rights. Doubtless the end of the litigation is not yet in sight.

The steady advance of continuous decantation during the past year has been another feature of the cyanide process. Conceding the great benefits which resulted from vacuum filtration, it is nevertheless true that some other method of treating slime has been earnestly sought. If one such could be discovered which would eliminate the capital expenditure and cost of operation for filters, another great step in advance would be taken. Judging from the variety of conditions under which continuous decantation has been success-

fully applied, it would seem as though the desired process had been found. Sound in theory and comparatively simple in operation, it seems destined to grow in favor. Certainly the filter decision referred to above cannot militate against the spread of continuous decantation; rather will it tend to call attention to the merits of a non-filtering system which is already a proved success.

Regarding the agitation of slime pulps in cyanide solution, there has been a tendency to adopt a system of successive treatments with intermediate change of solutions, placing thickeners between the agitators. This practice has resulted in better extraction than could be obtained in one agitation for a long period of time. There are indications that mechanical agitation, or rather a combination of mechanical and air agitation, is growing in favor as against air agitation alone. The combination offers the opportunity to apply the two features to the work for which they are best adapted. Another reason for seeking some other method than air agitation is the objection to the Pachuca tank. Its height is objectionable in mill design where all appliances must be inclosed in the mill building, and the power consumption is quite an item.

Zinc dust precipitation has grown in favor for obvious reasons, and many installations of this system have been made during the past year, even in small mills of, say, 100 tons capacity. Experiments have been made in the manufacture of a zinc ribbon as a substitute for zinc shavings, but while the material itself has apparently given satisfaction, mechanical difficulties in its manufacture in large quantities have not been overcome. The method tried was to allow molten zinc to run in small streams over a rapidly revolving water-cooled cylinder.

The use of warm cyanide solutions has been adopted in some places, particularly in continuous decantation plants, where it is quite as easy to add hot water as cold in compensating the moisture loss in the discharged pulp. The general impression has prevailed that warm solutions are beneficial in cyanide extraction, but doubt has been raised in at least one instance, where a tabulation of recoveries from various departments of the mill system failed to show the expected improvement in recovery by cyanide.

Taken as a whole the progress in cyanidation has been very gratifying. No radical changes have been made in the chemistry of the process, and improvement has been along the line of better mechanical application. None of the proposed modifications of the standard process has met with success, although several of them reached, and even passed, the Patent-Office stage.

Improvements in the Metallurgy of Lead.

The use of accessory processes in preparing lead ore for smelting, and the recovery of by-products, were the two most important lines of development in lead metallurgy in 1912.

The increasing quantity of concentrates offered to reduction works, and the corresponding decrease in production of crude lump ore, have necessitated the adoption of some method of preparing the former for the blast furnace. Under former methods of roasting concentrates the product was too fine to form a large part of the furnace charge.

The quantity of such material, however, was comparatively small, and by briquetting it with lime and flue dust it could be handled without undue loss; but with the great increase in quantity came an urgent necessity for preliminary roasting and agglomeration.

If we may judge from the wide adoption of the Dwight & Lloyd method of sinter roasting, this process is meeting the need fully. Not only has it proved beneficial in the smelting of concentrates, but it has demonstrated the value of "pre-digested food" for blast-furnace reduction. Furnace capacity is practically doubled when the charge is composed largely of sinter-roasted ore, and the smelting process runs more smoothly. Some Western plants are smelting in half the number of furnaces the same tonnage of ore formerly treated in all the stacks. This preliminary treatment has proved so satisfactory that one company has adopted the plan of crushing lump ore and sinter roasting it before smelting. At other plants where the Huntington-Heberlein process was adopted some years ago, the Dwight and Lloyd machines are being introduced. As to the relation of the Huntington-Heberlein process to the Dwight-Lloyd process some remarks by Dr. Heberlein in our columns devoted to Readers' Views and Comments in the present issue will be found of interest.

A commendable departure which was emphasized last year by the largest lead smelting company was the increased attention paid to the recovery of by-products, and the establishment of a technical research department. In the past, lead, copper, gold and silver have been the more tangible metals recovered, and these have received attention to the exclusion of others which have escaped unnoticed. Perhaps the centralizing of the industry, particularly the refining operation, has called attention to the minor quantities of other metals which gradually accumulate in flue dust, matte and bullion.

In any event, a number of metals are now being recovered as by-products from lead smelting and refining. Among these may be mentioned platinum, palladium, antimony, nickel, bismuth, tellurium, cadmium and arsenic. Some of these may not be of immediate commercial importance, and their cost may exceed their present value. On the whole, however, the indications are that the present policy of technical research will result in substantial economies in lead smelting, even if no radical changes in practice are evolved.

Developments in the Metallurgy of Copper.

Progress in the metallurgy of copper during the past year has been in the line of more careful dressing of ores, improvement in the basic-converting practice, and in the treatment of tailings.

In the dressing of ores much work has been done in the selection of the best type of machine for crushing jig middlings, the general practice being to reduce such material in either Huntington or Chilian mills. One company in Arizona, after a very extensive series of tests, has decided in favor of the use of Hardinge mills for this purpose.

Much work is being done in an effort to secure a suitable device for concentration of finely divided ore. The Wilfley

multiple-deck concentrating machine has been adopted in several plants. The Peck centrifugal slime concentrator has not made the success that was predicted for it, the difficulty being not in any defect in the principle of separation, but in the present inability to secure a machine that will "stand up" under the severe strain put upon it by the high velocity required for successful separation. A desliming device using the centrifugal principle, separating clayey material from finely divided silicious and sulphide material, makes a concentration of the sulphides practicable.

It is interesting to note in this connection the renewed use of the old round-table principle for the concentration of such fine material. The new tables are of a very modern type of construction, being made with frames of structural steel and in units of four decks.

Tailings from concentration of sulphide copper ores contain as a rule from one-half per cent to one per cent copper. Sooner or later efforts will be made for the recovery of the metal from this low-grade material. For many years, by leaching the old mine-dumps about Butte, many thousand pounds of copper have been recovered. This process, however, is very slow and requires for the best results a slightly acid water. The ferric sulphate usually present also is a valuable factor. Then, too, the mine-dump material is far more porous than concentrator tailings would be, the latter comprising material usually finer than one millimeter.

At one large plant a roasting-leaching method is being tried on a scale large enough to demonstrate its commercial value. The method consists in calcination in a McDougal furnace for the production of sulphate and oxide of copper, leaching this product with dilute sulphuric acid, and precipitating the copper by hydrogen sulphide formed by the action of sulphuric acid on low-grade matte.

The Hybinette process for leaching copper ores has been successfully applied in Norway. Ores which formerly were shipped to Sweden and to Germany are now treated locally. The ores are calcined with from 2 to 20 per cent sodium sulphate, the calcine is leached with dilute sulphuric acid and the copper electrolytically deposited from solution, insoluble anodes being used.

Wet methods have been in use many years, but without commercial success except in isolated cases. Progress such as that noted above give occasion for the hope that the many difficulties encountered by these processes may be overcome in the near future.

Only one or two plants in this country are now converting copper matte in acid-lined converters. Converting in basic lined converters has proved far cheaper, and, because of the much longer campaign made possible by the long life of basic linings, the capacity of a converting department is very greatly increased.

Duties on a single basic lining, in a converter approximately eight feet in diameter and twelve feet long, have been recorded as high as 20,000 tons, with 40 per cent matte. When these same converters were used with acid lining the average duty per lining was only about fifty tons. Steps are now being taken for the use of much larger converters. A converter recently put into use is 20 feet in diameter and has a capacity of over three hundred

tons of matte per day. What the duty per lining will be is hard to conjecture.

The thio-gen process for neutralizing smelter gases, by reduction of the oxides of sulphur with petroleum, aims at the root of the smoke problem, that is, the elimination of not only sulphur trioxide, which is accomplished by the Sprague and Cottrell methods, but also of sulphur dioxide, which is probably the principal cause of injury to plant life, particularly to conifers. If Mr. Young, who devised this process, proves it to be commercially applicable, he will have solved a very troublesome problem. Extensive tests were made in California during the past summer, but the results have not been made public, and so far as can be gathered there is still work to be done before the process can be considered a commercial success.

The Metallurgy of Zinc in 1912.

The situation with regard to the production of spelter has not changed greatly in the past year. In discussing processes for winning zinc from its ores, it must be kept always in mind that an ore-body of large size, such as the Butte and Superior, which is reported to contain 3,000,000 tons of 20 per cent zinc ore, can stand a great deal of costly experimenting, and a very expensive metallurgical plant, such as could not for a moment be considered for small mines.

It is safe to say that there is but one body of 15 per cent zinc ore in the United States with over a million tons actually in sight. There are not to exceed three with half a million tons each, and not to exceed eight with over one hundred thousand tons developed.

With large compact bodies of ore in this country more attention undoubtedly would be given to primary rather than secondary metallurgical processes, the aim being to produce spelter at the mine. There are so far but three primary methods to consider: retort-smelting, electric-smelting and electrolysis.

Practically all spelter now produced is made in retorts. That strong and well informed spelter manufacturers believe in the permanency of this condition is evidenced by their continued heavy investments in permanent smelting plants in the coal fields of Illinois. It is true that there have been two strong motives. First, the failure of the Kansas natural-gas supply, and, second, the possibility of marketing acid in the Central States; but permanent smelting and acid-making plants such as these are expensive affairs, and it may be taken for granted that the well-posted builders thereof have not made these investments without a most careful and thorough investigation of other possible methods. This is not the place to discuss the details of improvements in retort smelting. They are substantial but not radical.

Electric smelting of zinc ore is now being exploited on a commercial scale and at considerable cost in at least one plant. The information coming out from this side does not as yet offer much encouragement, although there is always hope for the electric furnace when its achievements in other lines are considered. Several of the best qualified experts in electric zinc smelting are continuing their development work quietly on an experimental yet gradually

increasing scale and many of the early serious technical difficulties have either been solved or brought near a solution. It is a slow, but apparently safe and sane development.

At least four serious attempts are being made by promoters of electrolytic processes to produce spelter commercially. In each case the electrolyte is a sulphate solution and insoluble anodes are used. With power at \$25 per horse-power-year or less, and with cheap fuel available, these processes can make a very high-grade spelter at a direct operating cost which compares favorably with that of retort smelting. The spelter produced is 99.9 per cent pure, which is one of the points strongly urged, since such material commands a premium in the market; but with any considerable tonnage of such material offered regularly the premium would be quite certain to disappear. Cheap fuel for roasting and cheap power for electrolysis are essentials, and they are not often found together in the immediate neighborhood of Western zinc deposits. A rather more serious objection to the processes is the heavy cost of plant, which is from two to three times that of a retort smelter of equal capacity. This probably limits the use of electrolysis to large ore bodies or to large custom works centrally located, where the plant cost can be distributed over a tonnage large enough not to raise total costs unduly. Perhaps the most attractive feature of these processes is the fact that a very high recovery of the gold, silver, copper and lead is made in a concentrated by-product suitable for subsequent lead or copper smelting at small cost. On ores rich enough in these other metals this recovery seems sufficiently important to give electrolysis a strong advantage. The coming year should add greatly to our positive knowledge of this subject, since thorough trials under the best conditions are quite certain to be made.

Considerable of the work done by the secondary, preliminary or preparatory processes brings us to the conclusion that here the small mine owner has apparently a much better chance. He finds such methods wasteful, yet profitable. Wet concentration is, of course, the most common of them, and needs no description. The progress of the year seems to be toward improved tables, better classification and large slime plants. Like the improvements in smelting these are substantial rather than radical.

Flotation is without doubt as well adapted to many Western ores as it is to those of Butte or Broken Hill, and will come into wide use as results become better known. The method has the advantage that it can be applied by the owner of the smaller mines.

Dry concentration has had a quiet year, but at least two new attempts will be made in 1913 on zinc ores; one in Colorado, the other in Arizona. The Colorado attempt will use the McKesson screenless sizer in the effort to get proper table feed, followed by Sutton, Steele & Steele tables. The Arizona attempt is not yet very fully worked out in detail. Several promising dry concentrating machines are being developed, but the difficulties in the past have not been so much that the jigs or tables failed to make products as that the machinery and methods for the preparation of the dry ores and handling of dust were not by any means satisfactory.

Magnetic and electrostatic separation continue to hold their own. Their field is comparatively narrow, being confined largely to the separation of certain sorts of mixed concentrates or middlings made by wet concentration methods, but this field they fill well. An interesting achievement is the success of the Huff electrostatic separator at Sunnyside mine, Eureka, Col., where 80 per cent of the material separated passes a 200-mesh screen, yet clean products are made at good capacity.

Leaching processes aiming to produce zinc oxide either for direct consumption as such, or for later conversion into spelter, are attractive on paper, but are no more successful metallurgically and financially than the hydrometallurgical processes for copper have been. If we had no other methods of winning zinc they could and would be used, but so far they have proved too expensive and troublesome.

At least two new proposals have been made during the year to extract the zinc as oxide from the slags of the American lead and copper furnaces. Results cannot be said to be satisfactory, but since such methods have been successful abroad it seems likely the troubles here are economic rather than metallurgical.

Preliminary fire concentration is being increasingly discussed and investigated in the West, particularly for the carbonate ores. There are places where fuel, labor and transportation conditions should apparently allow a low-grade zinc carbonate to be burned on grates to oxide, at a profit; such oxide to be shipped East for conversion into spelter. But here again the fact confronts the investor that such a plant could only succeed where backed by large and reasonably homogeneous ore bodies.

Just a Word to Promoters and Investors.

What Dr. J. E. Teeple says elsewhere in this issue on the necessity of early expert advice in the field of wood waste utilization, is true and timely and important far beyond the limits of that particular industry. It is a significant fact of the times that promoters and investors alike are beginning to think of chemical and metallurgical processes, besides mines, gas plants, electric lighting plants and trolley lines. It may have been simply a matter of taste which has invited this change of subjects or the public service corporations may have become troublesome. But whatever the reason, the fact is as stated.

This augurs well for the near future of chemical and metallurgical industries in this country. Both the honest promoter and intelligent investor are needed and needed badly. And the enthusiasm with which promoters and investors approach chemistry is delightful. But it is also dangerous. Too much is too often hoped for. As a single instance, plain miracles are sometimes expected by honest people from the electric furnace, like reduction without a reducing agent, etc.

A first advice to promoters and investors in their first venture in chemistry is, therefore, needed, and Dr. Teeple's article in this issue fills this want admirably. The quintessence of this first advice is that in order to promote a new chemical process to industrial life the first man to be seen is not a lawyer or a politician, but the very best technical expert who can be found.

Readers' Views and Comments

Sir Robert Hadfield on the Status of the Metallurgical Engineer.

To the Editor of Metallurgical and Chemical Engineering.

SIR:—With reference to the editorial in your November issue on "The Metallurgist in Steel," I very heartily agree with your conclusions, upon which may I be allowed to make a few remarks.

It has in the past been a puzzle to me to know why the "metallurgist" has not held a higher and better position in the scientific world than has apparently been the case. It has always been my object and aim to do my small share in raising his status. Is not the work done by the metallurgist even more valuable to the world than that done by any other profession from the point of view of adding to material comfort and convenience? Take away his work, and where, from the modern point of view, would those who live in the world be?

Startling as it may seem, the whole ground work of modern progress to-day turns upon the work done by the metallurgist. The mechanical and electrical engineer may design, but they one and all eventually have to come back to the men who produce material that is capable of meeting the required conditions of modern civilization.

In my presidential address to the Iron and Steel Institute I strongly emphasized this. In this connection I had some interesting correspondence with the able president of the American Institute of Electrical Engineers, Mr. Gano S. Dunn, who in his presidential address on the Relation of Electrical Engineering to Other Professions mentioned various classes of "human engineering," but omitted the metallurgical engineer. When I wrote him about this he answered that if he had had before him the facts mentioned in my presidential address, the metallurgist would have crowded out one of the other varieties of engineers. I take this as no little compliment, while at the same time being sorry for that class of engineer who was to be removed from his niche in fame. However, as his status is not mentioned there need be no broken hearts. We can each select the one who has least favor in our eyes. I suppose many of us would select the plumber.

Let me conclude by again saying how exceedingly valuable and just, so it seems to me, is your editorial on "The Metallurgist in Steel." It is most satisfactory to find your paper put forward such views on this subject.

London, England.

R. A. HADFIELD.

The Electric Steel Furnace and the Use of Titanium in Foundry Practice.

To the Editor of Metallurgical and Chemical Engineering:

SIR:—I just have read the communication of Mr. Petinot in your November issue with reference to my article on "The Electric Steel Furnace in Foundry Practice." His main objection is due to a typographical error in the original article. Instead of "lost heats" one should read "lost heads," or better, "sink heads," that is to say, the part of the cast piece destined to prevent the formation of sinking holes by feeding the piece with steel still in liquid condition.

This answers Mr. Petinot's objections to the working conditions of electric steel furnaces, but his remarks suggest some more observations.

The electric steel furnace permits one to obtain perfectly deoxidized castings of higher quality than those made in ordinary open hearth or converter practice. This fact is at present agreed to by all metallurgists and is proven by the continually increasing number of foundries adopting the electric steel furnace for the manufacture of high-grade steel castings.

Mr. Petinot concludes from his experiments with several methods of heat in an electric furnace that the deoxidation by calcium carbide in the slag is not always perfectly well ob-

tained. I do not doubt his experience, but I beg to state that in the electro-metallurgical steel industry the earlier theories or views as to the exact action of the slag and the effects of calcium carbide in the slag are to-day already subject to criticism. Here I simply want to state that the operation of electric steel furnaces up to 12 tons capacity with many thousands of heats in foundry practice for production of steel castings of the highest quality as well as for all sorts of fine steels has proven that the electric furnace is exceedingly well suited for the turning out of first-class deoxidized material.

Mr. Petinot does not agree with me as to the usefulness of silicon-titanium alloy like that indicated by me. I am well aware of the fact that the great development of the use of titanium in steel practice is due to American metallurgy and I fully agree with Mr. Petinot that titanium has an excellent effect in cleaning the bath from impurities. But I cannot share his opinion regarding the addition of silicon-titanium compared to that of ferro-titanium and ferro-silicon, and without looking for a theoretical explanation, I beg to state that my works have decided to manufacture and to use the former complex alloy after a series of systematical experiments in foundry practice.

Silicon-titanium alloy is practically free from carbon and of sufficient density to be added in the electric furnace before the tapping and without remaining suspended in the slag. The silicon combined to the titanium in the form of the said alloy facilitates the formation, in the bath, of a slag of very fluid condition and separating easily.

In all our experiments with the electric steel furnace silicon has always been found to be very low, and with the exception of some qualities of special steels, it is always necessary to add silicon to the bath. It seems that actual electric steel furnace practice—as far as I know—is now sufficiently developed to do away with the fear of any influence of an acid furnace cover on the silicon contents of the bath.

Ugine, France.

The Huntington-Heberlein Process.

To the Editor of Metallurgical and Chemical Engineering:

SIR: Having come back from a three months' trip through the States and Mexico, I now have found time to read your extra edition reporting the proceedings of the Eighth International Congress of Applied Chemistry, in which you give an extract of the most important papers read and of the discussions which took place.

I find that the statement of certain facts regarding the so-called Huntington-Heberlein process may cause a wrong impression of the merits of this process as compared with the Dwight-Lloyd process (see page 596, Vol. X., No. 9 A.).

What I intended to state and did state after Mr. Dwight's very explicit speech on the progress of his process was that the Dwight-Lloyd machine giving a roasted product of a relatively thin stratum, say 4 to 5 in. thick, did not cause further cost of labor for breaking, and for this reason in connection with lead ores also offered an advantage from a sanitary point of view.

I mentioned that during the last years, of course, Mr. Huntington and myself had also further developed and improved the Huntington-Heberlein process so as to treat up to 40 and more tons of material in 24 hours in a single apparatus, and that by wetting the roasted product and letting it fall from a higher level the inconvenience of heavier expenses for breaking the cakes and of the development of obnoxious dust was greatly diminished.

Regarding the physical quality of the product I did not and cannot admit the superiority of the Dwight-Lloyd product over the Huntington-Heberlein roasted agglomerate.

Frankfurt a.-M., Germany.

F. HEBERLEIN

The Rôle That Zinc Ferrites Play in Hydrometallurgy.

To the Editor of Metallurgical & Chemical Engineering:

SIR: At the present time there are many attempts being made to treat complex zinc sulfides by chemical leaching and subsequent precipitation. These attempts can be divided into two classes.

The first class used chlorine gas and makes a water soluble chloridized product. The second class avails itself of the familiar metallurgical roasting operation and then leaches with sulfuric acid or sulfurous or some caustic solution. Most of these proposals of either class use electrolytic decomposition of the solution for the preparation of the metal.

Whether or no the felicitous phrase "damn a wet process" and so consigning to the infernal abysses these numerous sincere and industrious strivings to increase our natural mineral wealth by applying the methods of the chemical laboratory to the works can be legitimately applied to the hydrometallurgical trials is, of course, a question to which the future alone can give a pragmatic answer. Possibly time will prove the contention of the advocates of the electric zinc furnace that it has certain innate metallurgical points of superiority over leaching apparatus. But, be that as it may, the great activity of experimenters in this country, Canada and England demand respect from all metallurgical engineers.

The question of roasting of complex zinc sulfides has a most direct and practical bearing on the hydrometallurgy of any wet process. The "old chloridizing" or sulfating roast with or without mixtures of salt or crude acid sodium sulfate has been known in the old Henderson process, in the Ziervogel process, and in the hyposulfite leaching of chloridized silver ores. In any process that depends on desulfurizing partially or completely with the idea of making a product soluble in any reagent, the physics of the process and the changes in the physical microstructure vitally affect the ease of solubility of the product. Indeed we are here in the borderland of physics and chemistry and the problem can be stated truly to be one of physical chemistry or of "physical metallurgy."

In heating up any stable substance such as fireclay, it assumes, according to temperature and time, a denser and harder structure or in short the play of atomic and molecular forces results in a configuration of braced and interlocked dynamism. This can be true either of the intra-molecular stresses or of the extra-molecular stresses. At any rate as a matter of practical fact the soluble quality of the roasted product will vary greatly and on holding a uniform quality it will be found that the whole question of practical success of the process will hang.

One of the chief of these chemical compounds that can be definitely isolated is zinc ferrite, $\text{ZnO} \cdot \text{Fe}_2\text{O}_3$ or $\text{Zn} \cdot \text{Fe}_2\text{O}_3$. This may be formed in the wet way or it can be formed in the dry way. In the wet way it is probably formed by the double precipitation of the oxides of iron and zinc out of a strongly ammonium chloride solution and drying in vacuo. Franklinite, a well-known ore of zinc is a zinc ferrite with part of the iron and zinc replaced by manganese. In the dry way it is simply made by heating an intimate mixture of zinc oxide and iron oxide together.

The writer found in 1903 that the solubility of this product in such reagents as ammonium chloride, ammonia, sulfuric acid, diminished greatly as the time and temperature of heating and the rate of cooling varied. Indeed by heating at about 1300 deg. C. for 12 hours I made a hard dense zinc ferrite that was practically inert chemically. I lay stress on the factor of time as affecting the solubility.

Now zinc blende which is the raw material which all of these processes use is always associated with some mineral form of iron sulfide. In the roasting of such ores preparatory to leaching the tendency is to make zinc ferrite and the more this tendency is allowed to exert itself the greater will be the difficulty of solution.

In a recent meeting of the Faraday Society there was a symposium on various phases of magnetism. In one of the

papers the author, Prof. E. Wedekind, pointed out how different salts where ferric oxide played the rôle of an acid, such as zinc ferrite and of the type $\text{M}_2\text{Fe}_2\text{O}_4$ like magnetic iron oxide or iron ferrite (Fe_2O_3 or ferrous ferric oxide) had certain marked ferro-magnetic properties. A long series of such salts as cobalt ferrite, calcium ferrite were given.

It is a long way from Broadway to the copper river district of Alaska, but modern commerce is so related. It seems a long way in the physical chemical world between the magnetic qualities of iron compounds to the hydrometallurgy of zinc. But the case of zinc ferrite suggests the possibility that calcium ferrite and numerous other ferrites are formed in roasting.

It seems a positive dictate of both experimental and theoretical chemistry that successful leaching of zinc ores can only be obtained by a careful investigation of this rather new field of physical chemistry—the formation of new insoluble compounds in the dry way. What little is known about it almost haunts one with the idea of what might be known of the subject—of the move of heaven and hell—than is dreamt of in our philosophy.

Hartford, Conn.

Code of Ethics of American Institute of Chemical Engineers.

To the Editor of Metallurgical & Chemical Engineering.

SIR:—In your December issue you published a letter from Dr. Joseph W. Richards regarding the Code of Ethics which was then before the American Institute of Chemical Engineers, and which since then has been adopted by the Institute. I was chairman of the committee that drew up the Code of Ethics, and Dr. Richards attended one of the meetings. At that meeting we tried to meet most of the objections which Professor Richards raised. The code having been adopted, it is perfectly proper for Professor Richards to advocate in a proper manner and place a reconsideration of the action by the Institute or to amend the code in such a way as seems desirable. I would like, however, to call attention to the following points:

It is a great pleasure for the members of the Institute to realize that Professor Richards does not require a Code of Ethics. It is to be hoped that no member of the Institute requires a code, but that is not the important question.

The important question is: Will a Code of Ethics be of assistance to the members of the Institute? Will it help to build up a higher ethical standard among them, and will it help to build up in the mind of the public a better appreciation of the moral excellence of the members of the Institute and the profession generally?

Some of the features of the code are undoubtedly unnecessary except as being a part of the logical presentation and development of the code. In such a presentation we naturally start with axioms which might appear gratuitous. As we read over the features of the code, it seems that the code offers valuable suggestions of methods of building up the profession. It urges mutual helpfulness and a general attitude of defense of chemists. It declares against sensationalism in advertising and against unreasonably low charges for professional work. It emphasizes the desirability of chemists giving credit to others wherever such credit is due. These and many other points are positive in their suggestiveness. Is any of us so good that he can overlook or ignore these positive suggestions? Are we all of us so helpful to our fellow chemists; do we always so avoid sensationalism; do we always so give credit to others for professional work, that it is unnecessary to be reminded on these points?

The Code of Ethics of the American Institute of Chemical Engineers gives backbone to our moral purpose. We can hardly conceive of it as limiting anyone's proper freedom of action. The most pronounced individualist will be as free under the code as he would be without it; but it adds to

such freedom a recognition of the profession as something of an entity—something that we should try to improve and exalt. I am confident that many members of the Institute joined it because they believed that it would raise, both ethically and intellectually, the standards of the chemical profession and believed that the indirect benefits derived from the Institute would be of infinite value.

The adoption of the Code of Ethics puts an emphasis on the ethical phase just as its educational requirements put an emphasis on the intellectual phase. Both are important parts of its reason for existence—neither should be ignored.

Brooklyn, N. Y.

G. W. THOMPSON.

Perkin Medal Awarded to James Gayley.

At the regular annual meeting of the Perkin Medal Committee the medal was awarded for 1913 by a unanimous vote to Mr. James Gayley for his dry-blast process in pig iron manufacture.

The Perkin Medal Committee consists of delegates of the Society of Chemical Industry, the American Chemical Society, the American Electrochemical Society, and of their New York Sections, and recommendations are made by the various national chemical societies of this country. The presentation of the Perkin Medal to Mr. Gayley will be made at the regular January meeting of the New York Section of the Society of Chemical Industry.

Electric Steel Furnaces.

As an indication of the present status of the electric furnace in the steel industry the following list of licenses of the Girod furnace will be found interesting:

Rubery Owen & Company, Darlaston, England; Gib. Ansaldo & Company, Genoa, Italy; Putiloff Works, St. Petersburg, Russia; Bethlehem Steel Company, South Bethlehem, Pa.; Krupp & Company, Essen, Germany; Oehler & Company, Aarau, Switzerland; Société John Cockerill, Seraing, Belgium; Stotz & Company, Kornwestheim, near Stuttgart, Germany; Stahlwerk Becker, Krefeld, Germany; Gutehoffnungshütte, Oberhausen, Germany; Ternitzer Stahlwerk, Schöeller, Ternitz, Austria; Danner & Company, Judenburg, Austria; Ungarisches Staats-Stahlwerk, Diosgyor, Hungary; Simonds Manufacturing Company, Lockport, N. Y., and two other American works whose name is not divulged at this time. One of these American works will install a 3-ton Girod furnace to be used exclusively in the manufacture of steel castings.

Thirty-Third Annual Report of the Director of the United States Geological Survey.

In the advance sheets of the director's report for 1912, Mr. George Otis Smith calls special attention to the need of a new building for the Survey. In considering the general unfitness of the buildings now occupied by the Survey, the director finds that they are inadequate from the point of view of the health and efficiency of the employees, as well as offering great risk from fire. The offices are crowded, and in the summer season some of them are too hot for occupancy. There is lack of fresh air and light, and too much noise and dirt from without; and the prospect of increasing the efficiency of the Survey under present conditions is remote.

The risk from fire is a menace second only to the existing danger to the health of the employees. The Survey's papers, records, maps, reports, etc., have an inventory value of \$4,840,000. If these were lost, it would be impossible to replace them without incurring an expense equal to their present value, and even then it would require observations extending over long periods of time to replace some of them. The director urges the need of adequate quarters, and states that plans for a building have been drawn and referred to the House committee on public buildings and grounds, of the Sixty-second Congress.

Oxygen from Liquid Air.

The Linde Air Products Company of Ohio has commenced the installation of Plant 5 in Detroit.

Preliminary work is now complete for the establishment of Plant 6 which will go forward at once in Boston. The new Boston plant will have a capacity of 15,000,000 cu. ft. of oxygen per annum and will involve an investment of approximately \$500,000.

The Linde Company is expanding its capacity in advance of requirements with a view to supplying local needs as rapidly as they develop at so low a price that the largest possible industrial use of oxygen will be made probable.

The use of commercial oxygen is strictly limited by small differences in selling price and the business must necessarily depend upon a very large output with a rather small margin of profit.

This calls for large investments and the Linde Company has the courage of its convictions.

Transactions of Eighth International Congress of Applied Chemistry.

There seems to be some misunderstanding among members of the Eighth International Congress of Applied Chemistry as to its printed report. This report will consist of 26 volumes of original communications, one volume of discussions, one volume on the Congress meeting itself and an index, or a total of 29 volumes or about 6500 pages. Prior to the Congress 24 of the 26 volumes of Original Communications had been printed; the two additional volumes of Original Communications have since been set up in type and the manuscript for the discussions and for the volume on the Congress itself has been practically completed since November 4, 1912, but is still awaiting manuscript from a few belated but important contributors, both here and abroad; the index cannot be prepared until all matter is in type and ready for printing, but the most of the work for that is finished for the first 26 volumes.

The date originally set for delivery of the entire Report was December 31, 1912. In view of the delay above described delivery to transportation companies cannot begin until toward the end of February, 1913; this will be automatic and will not be hastened by special inquiry; it is therefore requested that such inquiries be not made.

Bound volumes will not be delivered until the end of May, 1913; orders for bound volumes will not now be accepted. Members will be advised by letter at their last known address of the time their volumes left the Rumford Press at Concord, N. H., and by what transportation line. All inquiries as to reprints, corrections in papers appearing in volumes 1-24, imperfect volumes or sets and lost shipments, as well as all statements of change of address should be addressed to the Rumford Press, Concord, N. H.

The office of the Secretary of the Congress has been removed to 90 William Street, New York City, and all other communications should be so addressed.

Patent Reform.

Resolutions of American Institute of Electrical Engineers.

The Board of Directors of the American Institute of Electrical Engineers has adopted the following resolutions:

"Whereas, there are pending before the Congress numerous bills affecting and greatly modifying the Patent System in the United States, and

"Whereas, the Patent System has been, and is, a tremendous factor in building up the present industrial prosperity of this country, thereby greatly contributing to the prosperity of the country as a whole, and

"Whereas, any untoward change in the patent situation might disastrously affect this condition of industrial and general prosperity, and the conditions contributing to their continual augmentation, and

"Whereas, in view of the intimate relation of the Patent System to the general welfare, no action looking toward any radical change in the Patent System should be taken without most careful consideration, and

"Whereas, in our opinion, proper consideration of such important changes as are proposed can be had only by an unbiased, non-partisan commission, made up of men from various walks of life and not from any one vocation, or interest,

"Be It Resolved, that the American Institute of Electrical Engineers, acting through its officers and board of directors, respectfully urge the Congress of the United States that they provide for a Commission, made up of unbiased, independent, non-partisan men of such national standing as will command the respect of the whole country; and chosen from different walks of life; and not more than one from any one calling or interest; and serving without pay. Such Commission to hold public hearings, and otherwise, as may appear to them best, to make a thorough and careful study of the American Patent situation, and to prepare and submit a comprehensive report and recommendations to Congress for such changes, if any, as may, as the result of their study, appear to them expedient, whether in the Patent Office, in the method of court procedure, or in the organic Patent Law, and recommendations as to the Legislation they would propose for effecting said changes. And that we further respectfully urge that the Congress make ample provision for the expenses of said Commission, and

"Be It Resolved, that we respectfully urge the Congress of the United States to hold in abeyance all proposed Legislation affecting the Patent System in whatsoever way until such time as the said Commission shall have had ample opportunity to hold the said hearings, and make the said study and report, and

"Be It Further Resolved, that these resolutions be printed and a copy be sent to each Senator and Representative of the United States who is a member of the Senate or House Committee on Patents."

Mr. Ralph D. Mershon is the president and Mr. F. L. Hutchinson is the secretary of the American Institute of Electrical Engineers.

The Iron and Steel Market.

The slowing down which usually occurs in the iron and steel market at the close of the year was observed in December, but was less marked than usual in that the pressure for deliveries continued heavy. Buyers were as insistent as ever in urging the mills to better deliveries. In forward buying there was a notable decrease, except as to railroad buying, which continued heavy. In specifications against contracts already placed the month made a good showing, though the total tonnage specified was not as great as that of November, the decrease being probably due to the fact that some contracts, nominally written to last to December 31, had already been worked out.

There were no important price changes during the month. Effective December 16 the American Steel & Wire Company advanced its prices on wire products \$1 per ton, putting nails on the basis of \$1.75 per keg. Such an advance had been made by two or three independents about the middle of October, in the expectation that a general advance would thus be precipitated.

The scarcity of crude steel became still more acute in December, a point being reached at which there was practically no quotable market. The regular large producers had long been out of the market, and only occasional lots could be picked up from brokers or from outlying mills. An Alabama interest, for instance, offered a moderate tonnage in the North for next year's delivery, and succeeded very quickly in selling on the basis of about \$20, Pittsburgh.

The famine in unfinished steel has greatly disturbed many of the independent finishing mills, particularly sheet and tin mills, which must depend upon purchased steel for their operation. The prospect is that some of them will lose time in the first quarter of the new year from not having steel. The

scarcity of unfinished steel, however, is a natural outcome of conditions. In the first place, the normal alignment of the steel industry, the alignment that has prevailed ever since the steel industry reached important proportions is that of their being an excess of finishing capacity over steel-making capacity. In the laying out of an individual plant, with diversified product, it is always regarded as desirable to have an excess of finishing capacity, for if perfect balance could be secured in mechanical operation, such balance would be impossible in the market. A mill cannot be certain of selling its output in precisely the proportions the different finishing mills would make, if operated full. It is easy to slow down or to close a given finishing mill, whereas to slow down the steel-making unit is expensive, there being little reduction in overhead. When the individual plant is naturally planned for more steel finishing than steel-making capacity, so much more is the alignment in that direction when the steel-making unit is under one ownership and the steel finishing unit is under another. When, therefore, there is a market which would involve the operation of all the finishing capacity, there is not enough steel to supply it.

Another cause of the famine in steel is the continued sharp trend in demand toward open-hearth steel. The greater portion of the finishing capacity of the country chances to be so arranged that it can roll either Bessemer or open-hearth steel, whereas there is practically no flexibility in the steel-making units. The Bessemer plants can make only Bessemer steel and the open-hearth plants only open-hearth. For the idle Bessemer plants to relieve the scarcity involves their making billets or sheet bars for the market, and this they are not all equipped to do. We said there is "practically no flexibility" in the steel-making units. There is none at the moment, but there is some by rearrangement, whereby Bessemer vessels may sometimes be made to form the first link in the practice of the duplex process, either by using open-hearth furnaces already built, or by building them. A recent instance of the latter is the erection in the past year of two 250-ton tilting furnaces by the Lackawanna Steel Company, to practice the duplex process with existing converters.

Finally, billets and sheet bars have been made scarce by the heavy demand for rails, since many of the mills are interchangeable as to billets or rails, sheet bars or rails, or the whole three products. Rails are a finished product, sold to consumers, and a producer having the choice of selling rails or sheet bars, or rails or billets, chooses the rails apart from considerations of price and cost of manufacture, regarding rather the general principle that the actual consumer, rather than a detached finishing mill, presents the trade which in the long run it proves best to serve.

Pig Iron.

The pig-iron market was practically stationary as to prices during December, and was rather slow as to transactions. There was a strong undertone to the market, which did not depend upon current demand, but rather upon the facts that the operating furnaces were already well sold up, and that on account of the very high prices ruling for coke it was difficult to start any of the idle furnaces. The only advances over quotations in last report are of 25 cents in foundry iron in the valleys and in eastern Pennsylvania. We quote: Bessemer, \$17.25; basic, \$16.50; No. 2 foundry, \$17.50 to \$18; forge, \$17 to \$17.50; malleable, \$17 to \$17.50, f.o.b. valley furnaces, 60 cents higher, delivered Pittsburgh; No. 2N foundry, delivered Philadelphia, \$18.50 to \$18.75; No. 2 foundry, f.o.b. Chicago furnaces, \$18; No. 2 foundry, Birmingham, \$14 to \$14.50.

Steel.

The market has become purely nominal, as already noted. Prices last quoted, which were based upon actual transactions, and which would probably prevail had the large mills any tonnage to dispose of, are as follows: Bessemer billets, \$27; sheet bars, \$27.50; open-hearth billets, \$28; sheet bars, \$28.50, f.o.b. maker's mill, Pittsburgh or Youngstown. Under special cir-

cumstances, sales of open-hearth billets have been made at \$29, Pittsburgh. Rods are \$30, Pittsburgh, with sales at that figure.

Finished Steel.

Regular steel prices showed no important change in December, there being simply an advance of \$1 a ton in wire products. On the majority of products premiums ruled for early deliveries, but such prices cannot be quoted, as the premiums increase the smaller the order, with no definite limit, and also increase with the nearness of delivery. In general there are many products which have commanded premiums of \$2 to \$4 a ton in carload lots for delivery within one to three weeks.

Regular prices for forward delivery are given below, prices being f.o.b. Pittsburgh unless otherwise stated:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.50 cents.

Shapes, 1.50 cents.

Steel bars, 1.40 cents.

Common iron bars, 1.65 to 1.75 cents, Pittsburgh; delivered Philadelphia, 1.67½ to 1.75 cents; f.o.b. Chicago, 1.60 to 1.65 cents.

Steel hoops, 1.50 cents.

Sheets, blue annealed, 10-gage, 1.65 to 1.75 cents; black, 28-gage, 2.25 to 2.35 cents; galvanized, 28-gage, 3.40 to 3.50 cents; painted corrugated, 28-gage, 2.45 to 2.50 cents; galvanized, 3.45 to 3.50 cents.

Tin plates, \$3.60 for 100-lb. cokes.

Merchant steel pipe, ¾ to 3-in., jobbers' carloads, 80 per cent. off list.

Steel boiler tubes, ¾ to 4½-in., 71 per cent. off list.

Standard railroad spikes, 1.85 to 1.90 cents.

Button head structural rivets, 2.20 cents; cone-head boiler rivets, 2.30 cents.

Tubular Goods Revision.

Under the lead of the National Tube Company, which on November 27 announced to its customers and competitors the revised lists it would work under beginning January 1, 1913, a general change has been made in merchant pipe and boiler tubes.

The old merchant pipe list carried the weights per foot and thicknesses of wall based upon wrought iron, and when steel was adopted, with about 2 per cent greater specific gravity, the mills departed from the standard thicknesses and adhered to the standard weights per foot. The present revision restores the old thicknesses, thus increasing the weights about 2 per cent, but the computations are more exact than formerly. Next, the list prices per foot are revised so that they conform more closely to the principle of making the list price produce a price of 10 cents per pound. Until now there have been made two weights in merchant pipe, 6-in. and under, the "card weight" conforming to the card, and "merchant weight," a weight indefinitely lighter, and sold in the market at one point discount (about \$2 per net ton) less than the price of the card weight.

The revision of weights and list prices made on the whole a slight advance in prices per foot, though a slightly greater reduction in prices per pound, and at unchanged discounts the net prices per foot would be slightly advanced. To avoid the appearance of making any profit out of the rearrangement, when it is made solely in the interest of improving the quality, the manufacturers have made the old discount on merchant weight apply to the new full weight pipe. Thus the price per foot of card weight is slightly reduced, and a buyer formerly taking merchant weight secure full weight at a very slight advance compared with the much greater weight furnished.

The boiler tube list was somewhat similarly revised, but as list prices were somewhat reduced and as contracts were on back orders well into the new year, the discounts were reduced at one point, thus obtaining a slight advance.

The Non-Ferrous Metal Market.

General dullness has characterized the non-ferrous metal market for December. Copper has been stagnant, lead has been greatly reduced in price, tin is offered freely without premium for immediate delivery, and spelter has been offered liberally at low prices without finding buyers.

Copper.—Since our last report Lake copper has had only a nominal price, and little business has been transacted. The principal sellers have maintained the price, and outsiders have sold the metal at concessions. Moderate sales have been made in electrolytic. The impression prevails that consumers cannot much longer stay out of the market. The latest quotations are: Lake, 17½@17¾ cents; electrolytic, 17.35@17.40 cents.

Lead.—Twice since our last report the principal producer cut the price, first to 4.50 and later to 4.35 cents. In each case the cut was met by other sellers, who reduced their prices correspondingly. In spite of the low prices prevailing, little business has been transacted. The metal is quoted at 4.15@4.17½ cents, St. Louis, and 4.30@4.35 cents New York.

Tin.—Lower prices prevailed in the London market, and this developed a fair business with American consumers. The premium on spot tin has disappeared, and December tin was quoted at 49¼ cents.

Spelter.—Prices have continued to decline, and some business has been effected at 7.10 cents. The prospect of importations of foreign spelter has affected the domestic market, and removed the customary differential between New York and St. Louis markets. The latest quotations are 7.05@7.10 cents, St. Louis, and 7.10@7.20 cents New York.

Notes.

Metal shipments from Nome, Alaska, for the navigation season of 1912 have been made public by R. W. J. Reed, deputy collector of customs. Placer tin mined in the vicinity of Nome, 173 tons; placer tin shipped, 129 tons; gold dust and bullion shipped, 160,079.69 oz. valued at \$2,931,478.26. The gold output for the season probably will be increased by about \$100,000 by dredges operating during November.

Pebbles for the Hardinge regrinding mills at the Tomboy mill, Telluride, Colo., are prepared at the mill from selected pieces of mine rock composed of rhodonite and quartz. The rock is broken into rough spherical shapes and charged into the mills at the rate of about 170 lb. per day. Some of the worn pebbles show ridges of the hard quartz above the general surface of the rhodonite. The pebbles give satisfaction, and are used in preference to imported pebbles which would cost about \$28 per ton delivered at the mill.

The Bureau of Mines has recently issued the following publications of interest to mining and metallurgical engineers: *Technical Papers*, No. 22, Electrical Symbols for Mine Maps; No. 24, Mine Fires; No. 25, Determination of Water in Petroleum and its Products; No. 26, Determination of the Sulphur Content of Fuels, Especially Petroleum Products; No. 28, Ignition of Gas by Standard Incandescent Lamps; *Bulletins*, No. 43, Fuel Values of Gasoline and Denatured Alcohol for Internal Combustion Engines; No. 44, First Mine-Safety Demonstration; No. 45, Investigation of Explosion-Proof Motors; No. 47, Notes on Mineral Wastes. These publications can be had on application to the Director, Washington, D. C.

Timber Preservation at the Homestake.—The cats and tanks at the Homestake mill, South Dakota, are of California redwood, with the exception of a few thickening tanks which are of cypress. They are painted on the inside with P. & B. paint, and on the outside with a mineral paint containing more or less red oxide of iron. A timber-treating plant is installed for impregnating wood with creosote or dead oil of coal tar. The usual treatment is a hot bath of two hours' duration at a temperature averaging 216 deg. Fahr., followed by a half-hour contact at 180 deg. Fahr. or 190 deg. Fahr. The cost is about ten cents per cubic foot. Railroad ties and 2-in. plank for mortar blocks are thus treated.

Notes on Chemistry and Metallurgy in Great Britain.

(By Our Special Correspondent)

The Iron Market.

The effect of the steadily increasing demand for iron, both at home and abroad, which set in before the middle of this year, has been to send up prices to figures which have not been reached since 1900; and there is every probability that the rise will continue, because the demand seems likely to become still greater. Many manufacturers are showing disinclination to make further purchases of pig-iron at the present high rates, whilst the pig-iron makers assert that the price of manufactured articles has risen proportionately higher than that of the raw material—a contention which certainly appears to be supported by a study of the quotations during the last few months; and, in any case, the advance unquestionably began with manufactured products before the price of pig-iron increased.

At the close of 1911 Cleveland warrants stood at 50s. 10d., and the stock at Middlesbrough amounted to rather more than half a million tons, whereas at the end of last October it was only slightly over a quarter of a million tons, and the quotations touched 67s. Since the coal strike both coal and ore have increased in cost, and the replenishment of the stock depleted as a consequence of the strike could only be possible at greater cost; but had there not been any coal strike the increased activity in the iron trade would have been felt only a little earlier, and an uninterrupted production of pig-iron would not have materially affected the advance in price during the last three months or even sooner.

There are now very few idle furnaces in England or Scotland—although the total number now in blast is only some six more than at the end of last year—but their output is inadequate to meet the requirements of the iron and steel works, which are in turn unable to keep pace with the demands of the consumers. It is not magnifying the truth to say that every iron and steel works is being run at the fullest capacity; many works are being extended to cope with the increasing influx of orders; and it is anticipated that unless the supply of raw iron can be considerably augmented the inquiry for the home market will, at no very distant date, be such that it will absorb almost the whole of our production and very largely reduce the amount available for export when still heavier shipments than are being made now will in all likelihood be called for.

The question is how the increased consumption of pig-iron is to be met soon enough. The output from the furnaces now in operation cannot be enlarged to any great extent, and the provision of new ones in sufficient numbers is not practicable in a few weeks, while the localities in which electric smelting could be quickly put into practice are very few and even in these the working costs would be prohibitive for iron ore reduction in England. The old proverb, "No pleasure without pain," is emphasized by the embarrassing situation resulting from a most gratifying revival of the iron trade.

Poisonous Gases from Oilfields.

A paper on this subject was read by Mr. H. S. Shrewsbury before the Society of Public Analysts at the meeting on Nov. 6. Recently a negro was killed by breathing the gas at the bottom of a pit under an oil derrick close to the Pitch Lake at La Brea, Trinidad. The pit was some 10 ft. deep and surrounded the casing of the tubular oil well, from which the gas most probably overflowed into the pit. While working in the pit the man became giddy and had to be helped out. Twelve hours later he was dead.

A sample of gas taken from the top of the oil tube was analyzed by the author, who found that its composition was: sulphuretted hydrogen, 0.1 per cent; carbon monoxide, 1.1; saturated hydrocarbons, 4.4; unsaturated hydrocarbons, 2.5; oxygen, 8.7; carbon dioxide, 11.9; hydrogen, 18.8; and nitrogen, 52.5 per cent. Assuming all the oxygen and some of the nitrogen to be derived from the air, the amount of air present was 43.4 per cent, and the composition of the gas as it issued

from the ground was: sulphuretted hydrogen, 0.2 per cent; carbon monoxide, 1.9; unsaturated hydrocarbons, 4.4; saturated hydrocarbons, 7.8; carbon-dioxide, 20.9; hydrogen, 31.4; and nitrogen, 33.4 per cent.

A Wynter Blythe states that 0.05 per cent of sulphuretted hydrogen in air is the maximum that can be breathed with safety; that 0.08 is dangerous, and 0.1 to 0.15 fatal to human life. According to Haldane, more than 0.15 per cent of carbon monoxide is dangerous, and 0.4 per cent would kill in a moderately short time. The gas as it issues from the ground is extremely poisonous; and when diluted with 43 per cent of air would kill in a short time—as indeed it did.

The author visited the Pitch Lake and observed that the surface is covered with little pools and channels of water through which gas is constantly bubbling, and gas also issues from the pitch itself. This gas has exactly the same odor as the sample described—the small percentage of sulphuretted hydrogen mixed with the hydrocarbons producing a sweet and tar-like smell. The author also witnessed the interesting fact that small fishes live in the pools through which the gas bubbles, notwithstanding its poisonous character. It appears to your correspondent that air containing 11.9 per cent of carbon dioxide is sufficiently poisonous without the CO and H₂S.

The Granular Structure in Metals.

It is a matter of common knowledge that reheating steel at temperatures below 900° C. renders the structure of the metal granular and induces brittleness. F. Robin (Comptes. Rend., 1912, 155; 716-719) states that he has found that other metals are similarly affected, and that hammering, deformation and compression likewise tend to develop a coarse, granular structure. In the case of local deformations, such as bends, the granules formed in the deformed area appear to mutually limit their development; while just outside this area their development is greater and extends gradually into the unaltered portions. When an annealed metal is locally hardened by forcible deformation, such as shearing, punching, or bending, and is re-annealed at various temperatures (presumably below the change point) for about half an hour, the invasion of the unchanged area by large granules is distinctly noticeable after five minutes. Such granules appear to be subject to much the same conditions as those produced by annealing, and they extend as far as 7 to 12 mm. into the unaltered region.

The extensive manufacture of articles from stamped, bent and perforated sheet metal invests this subject with a considerable degree of industrial importance. The remedial measures suggested by the author are, for iron, heating to above 900° C., and for non-ferrous metal, the addition of other metals.

Electrolytic Tanning.

A process of tanning by electrolysis has been devised by Dr. L. A. Groth, and a small plant for demonstration purposes on a commercial basis is being put down at Mr. C. Smith's tanyard, Kidderminster, by the Local Electric Lighting and Traction Co., under the direction of the inventor.

The time required for tanning heavy hides by the ordinary processes extends to several months; and Dr. Groth claims that by his method they can be purely and effectively tanned in six weeks, yielding a leather of very high quality.

The operation of the plant is practically automatic, and the necessary attendance throughout is furnished by two lads; whilst the cost of production is said to show a very considerable saving as compared with that of tanning by the usual processes. An ingenious system of automatic control is designed to prevent injury to the skins or the tan-liquor, and any departure from normal conditions is at once signalled to the attendant by bell and the lighting of a lamp at the spot requiring attention.

A Reinforced Concrete Water Main.

At Luton, Beds., a ferro-concrete rising main about a mile long and having an interior diameter of 27 in. has been constructed by a London firm. The steel reinforcement measures

$2\frac{1}{2}$ per cent of the volume of the concrete, which has a thickness of 3 in. and is without lining of any description. The main stood a continuous test at a pressure of 60 lb. per sq. in., and when completely filled the loss after standing twelve hours was only four gallons. As the valve at the lower end was not readily accessible and might possibly not have been quite tight, the main was reported as thoroughly water-tight. The lowest tender for cast-iron pipes of the same capacity was £2-2-7 per yard, and the cost of the concrete main, delivered at Luton, was £1-7-7 per yard.

Castner-Kellner Alkali Co.

The annual meeting of this company was held late in November in London. The chairman, Mr. G. W. Balfour, announced that the net profit on the year's working was £172,062, against £178,853 for the previous year; but the reduction was due to special circumstances. The depreciation reserve against patents, land, buildings, etc., valued at £737,000, now amounted to £322,500, out of which sum £60,000 had been invested by reducing their debentures.

The general reserve of £177,500 was invested in readily realizable securities, and could be employed in any way the directors chose. Given continued prosperity, the directors might consider the advisability of reducing the sum carried to general reserve in future and increasing the dividends. A final dividend of $1\frac{1}{2}$ per cent was agreed to, making 20 per cent for the year.

Alby Carbide.

The sixth annual general meeting of the Alby United Carbide Factories, Ltd., was held on Nov. 28 in London, under the presidency of Mr. A. E. Barton, chairman of the company, who said that the profits for the year ended June 30 showed an increase of practically 100 per cent on those for the previous year, which in turn were 58 per cent greater than in 1909-10. The balance sheet shows that the net income for the 12 months June 30, 1911-1912 was £72,702, and this sum, with £493 brought over, suffices to write off £6,514 for depreciation; £2,000, the balance of the Atkins Acetylene Dry Generating; £37,012, the entire amount of preliminary expenses, and to provide a final dividend of 3 per cent on the ordinary shares, making 6 per cent for the year, leaving £4,097 to be carried over. The dividend for the last financial year on the shares held by the company in the Meraker Company amounted to nearly twice the investment.

The present output of the Odda factory is 32,000 tons of carbide per annum, and in order to enlarge the works for turning out 80,000 tons per annum, the capital has been increased during the past year to £550,000 by issue of 150,000 $\frac{1}{2}$ per cent accumulative convertible preference shares. The company's interest in Alby Carbide Works (Sweden) has been acquired by Nitrogen Fertilizers, Ltd., for 142,380 £1 shares in that undertaking, and by the purchase of 50,000 additional shares the company now holds 192,380 shares out of a total of 220,000 in Nitrogen Fertilizers, Ltd.

Engineering Imports and Exports.

The returns issued by the Board of Trade again show substantial advances in the value of both imports and exports in the ten months ended on October 31 as compared with the same period of last year. Imports of iron and steel, including manufactures, totalled £10,489,072, an increase of £1,380,752; and exports amounted to £39,523,957, an increase of £3,719,742. Imports of other metals, including manufactures, are valued at £25,588,083, an increase of £2,582,495; whilst exports reached £10,014,596, an increase of £944,294. In electrical goods the imports are put at £1,176,199, a rise of £32,307; and exports went up to £1,715,449, an improvement of £1,458,481. Machinery was imported to the value of £5,645,823, an increase of £804,204 and was exported to the amount of £27,502,255, an increase of £2,077,878. Imports of new ships were £26,652, a fall of £4,441, but exports were £5,673,942, a rise of £1,260,879. The figures for October solely show increases all round. Imports of iron and steel were £349,706 higher and exports

were £1,022,072 better than last year; imports of other metals rose £1,082,431, and exports improved by £284,910; imports and exports of electrical goods went up £8,754 and £250,563 respectively; machinery shows increases of £219,113 in imports and £537,435 in exports; and imports of new ships rose £1,267, whilst exports were £867,310 better.

The aggregate increase in the value of the imports for the ten months is £4,798,848, and that of the exports is £9,441,265. Taking the decrease in the imports of ships as equivalent to a similar increase in exports, the net excess of increase of exports over imports is £4,676,758.

Market Prices for November.

Copper has been quiet on the whole, with tendency to rise about the middle of the month. Starting at £74.10 it had reached £77.10 by the 19th, and was over £78 on the 20th. On the 28th it only showed £77.15 and closes £76.10.0.

Tin opened at £229.5 and was fairly active, being at £229.15 at middle of month. A week later it was £227, and closes at £226.

Pig Iron (Scotch) has been quiet, with harder tendency towards the end of the month. Starting at 72/- it dipped a shilling on the 6th, recovering on the 7th. It commenced to rise on the 12th, and had reached 73/- by the 19th, and closes 73/10 $\frac{1}{2}$ d.

Cleveland has been in sympathy with Scotch pig, opening at 66/-, dropping on the 6th and rising on the 12th, it reached 67/9d. by the 28th, and closes at 67/2d.

Hematite has been slowly but steadily rising. Opening at 80/-, it reached 81/10 by the 19th, and closes at 82/-.

English Lead has fallen throughout November. Starting at £19.5, it was under £19 by the 5th, and continued to decline, reaching £18.15 on the 13th and £18.12.6 on the 21st. It closes at £18.10.0.

The Electric Furnace in the Production of Iron from Ore

A critical discussion of the present status and a comparison of the Scandinavian and Californian practices, by D. A. Lyon

AS is well known, the electric furnace, under favorable circumstances, may be used in the iron and steel industry for the production of metal from the ore, and later for the refining of this same metal into the grade of steel desired.

Conditions Favorable to the Use of the Electric Reduction Furnace.

It was pointed out by the Canadian Commission in their Report of 1904, that the prime pre-requisite for the use of the electric furnace in the reduction of iron ores, is cheap electric power. The large amount of experimental and practical work which has been done since that time has only emphasized this fact. The electric furnace, therefore, has not been developed as a competitor of the blast furnace, but, as is the case in Norway and Sweden, for the purpose of keeping alive an industry which finds itself confronted by conditions unfavorable to a continuation of blast furnace practice, due to the increased cost of charcoal; or for the purpose of making possible the development of the iron industry, as is the case in California, where the iron industry has never been developed, due to the cost in that section of the country of both charcoal and coke.

In each country, considerable experimental work was first done and then the furnace was tried out on a commercial scale. As was to be expected, the problems which presented themselves at the outset of the work were not solved at once, and there are still problems which are awaiting a more satisfactory solution than has so far been attained, but satisfactory progress is being made in this direction. That the electric iron ore reduction furnace has entirely passed the experimental stage is evidenced by the situation in California and Scandinavia.

The Scandinavian Practice.

Due to the large number of articles descriptive of the work in Sweden, which have previously appeared, it will not be necessary in this connection to do more than to refer to them and to state briefly the status of the electric reduction furnace in Scandinavia at present. (See also Oct. issue, 1911, p. 525.)

As a result of the successful operation of the furnace at Trollhättan, three other iron electric reduction furnaces are now being operated in Sweden¹ which together with the furnace at Trollhättan represent a total of 12,000 hp that is being used for electric reduction furnace work in that country; in

Norway there is one 3500-hp furnace in operation and one 3500 hp and three 3000-hp furnaces in the course of construction, while in Switzerland one of 2500-hp is being built.

As was likewise pointed out in the September, 1912, number of this journal, the Uddleholms Company, at Hagfors, Sweden, are increasing their electric furnace installation by the addition of three more furnaces and will probably substitute electric smelting altogether for their blast furnace work. It is also a significant fact that the plant at Trollhättan, which was built by the Jern-Kontoret, of Sweden, purely for the purpose of determining the feasibility of attempting to reduce iron ores in an electric furnace, has been sold by the Jern-Kontoret to the Degerfors Iron Company, and will be worked by the latter company as a commercial proposition from now on. The Degerfors Company is an old-established company, who make very high-grade material, and so it is not a case of a new concern taking up with a new venture, but one with long experience in the business, who have had ample opportunity to carefully study the feasibility of electric reduction furnace work under the conditions prevalent in Sweden, and who, as a result of their study, have satisfied themselves that the electric furnace will meet their requirements. In fact, the old saying, "the proof of the pudding is the eating thereof," would seem to apply as regards the use of the electric reduction furnace in Sweden.

FIG. 1.—SECTIONAL ELEVATION OF TROLLHÄTTAN FURNACE.

Some of the Difficulties That Had to Be Solved.

If a study be made of the drawings of those furnaces which have been tried out experimentally, it will be noted that in most of them an attempt was made to construct a furnace somewhat similar to a blast furnace, and to introduce the electrodes into the stack of this furnace at that point where the tuyeres are located in the former. All those who tried this soon learned that it was practically next to impossible to maintain the furnace walls adjacent to the electrodes. There was thus evolved as a matter of necessity the type of furnace construction which was finally adopted by the Swedish experimenters and such as is shown in Fig. 1². By referring to the same it will be noted that the furnace consists of two separate parts, namely, the crucible or hearth, superimposed above which is a shaft or stack. One of the most serious difficulties that had to be overcome in the perfecting of the electric reduction furnace was the maintenance of the crucible walls and roof. Such a construction as shown in Fig. 1 solved the difficulty as it meets the

¹A list of electric reduction furnaces now in use and in the course of construction in Europe will be found on page 539 of Vol. X of this journal.

²Those caring for further information in regard to the work of the Swedish experimenters are referred to the article of Lars Vingstom on "The Electric Shaft Furnace at Dönnarriet, Sweden," which appeared in this journal, Vol. VIII, page 11.

necessary pre-requisites, namely, keeping the end of the electrode dipping into the charge, as far removed from the side wall as possible, and second, keeping that part of the crucible out of contact with the charge at the point where the electrode enters the crucible. The reason for having to observe these precautions is due to the fact that the heat is excessive at that point where the electrode comes in contact with the charge, and hence this point should be as far removed as possible from both the side walls and roof of the crucible, in order to prevent the destruction of same through fusion.

The Electrode Problem.

When the demand was first made upon the manufacturers of electrodes for large electrodes of say 20 in. in cross section and 72 in. long, they experienced considerable difficulty in furnishing an electrode which would not go to pieces when put into commission. This caused considerable loss and annoyance to those attempting electric reduction and steel furnace work. Even if the electrode did not go to pieces, as soon as one-half to two-thirds of the same had been consumed it became too short for further use, and those unused portions represented a considerable item of expense. At the present time it is not only possible to obtain quite satisfactory electrodes, but also to

Although at one time or another the Shasta Iron Company has planned to make pig iron from this ore, nothing definite was done in regard to the same until the summer of 1906. At this time the possibility of smelting this ore by electricity was brought to the attention of Mr. H. H. Noble, president of the Northern California Power Company. Due to Dr. Heroult's connection with the experimental work which had been done at Saulte Ste. Marie, he was commissioned to construct a plant for the purpose of treating the ores above mentioned. The place selected was at a point on Pitt River, near the mines. This place was named Heroult and is still known by that name.

In July, 1907, the first furnace having been completed, experimental work was begun. This furnace was a 1500-kw, three-phase furnace of the resistance type. It was soon found that the type of furnace first used presented mechanical difficulties which made its commercial use impracticable, and so it was closed down. A sketch of this furnace is shown in Fig. 2. In construction the crucible resembled a long, elliptical-shaped iron box. The bottom was made of heavy cast-iron plates, into which had been cast cast-iron lugs or pins, and upon the iron plates was tamped a carbon bottom made of carbon paste. The bottom plates were connected with the bus bars in such a manner as to form a neutral in the three-phase system.

The electrodes passed through the roof, as shown in the sketch. They were suspended from copper holders which were water-jacketed. The charge was fed into the crucible through the pipe (B), and the gases from the crucibles passed up around (B) into (A), the idea being to thus preheat the charge in (B) by burning the gases around (B), air being admitted for that purpose through slots in the outer pipe just above the roof of the crucible. These pipes, however, proved too small, and the charge in them became so hot as to hang, and so they had to be done away with. It was also found impossible to maintain a roof over the crucible, and so the furnace was finally operated as an open-top furnace. Several tons of A No. 1 foundry iron were made in this furnace, and later it was used for making ferrosilicon, but was finally closed down and removed in order to make room for the type of furnace subsequently adopted. After the closing down of this furnace, experimental work was conducted in a 160-kw single-phase furnace, and from the results obtained in this furnace and its methods of operation a 1500-kw, three-phase furnace was designed and built. This furnace was practically the same in construction as is the furnace shown in Fig. 1. In other words, there was developed simultaneously in Sweden and in California a similar type of furnace, although neither the Swedish inventors nor those engaged in the work in California knew of the other's work. The development of this type of furnace was continued until the spring of 1911.¹ At that time, acting upon the advice of the consulting engineer then in the employ of the Noble Electric Steel Company, a radically different type of furnace was constructed. The object aimed at in the new design of furnace was to secure one which would be as easily controlled, so far as the regulation of the nature of the charge was concerned, as is the present open-hearth steel furnace. This furnace was not a success.

Another type was then hit upon, and this type has since been developed into a commercially successful furnace. It is shown in Fig. 3. By comparing Figs. 2 and 3 it will be seen that the furnaces shown in each are quite similar, but in a recent article descriptive of the plant of the Noble Electric Steel Company it is stated that "this resemblance is only general."

Electric Iron Reduction Furnace in California.

The following information in regard to this furnace and its operation has been furnished the writer by the secretary of the Noble Electric Steel Company, and is chiefly taken from a re-

FIG. 2.—HEROULT THREE-PHASE FURNACE FOR SMELTING IRON ORE.

avoid the waste above mentioned. This is done by joining a new electrode to the butt end of an old one, as is done at Trollhattan² and at various other places.

So far our remarks have been applicable alike to the California practice and to the Scandinavian practice. It will, however, at this point, be necessary to discuss each practice separately, as they are at the present time radically different from each other. In order to understand the situation more clearly, it may perhaps be well to briefly outline the development of the electric reduction furnace as it has taken place in California.

The Development of the Electric Reduction Furnace in California.

For twenty-five years or more a company known as the Shasta Iron Company has owned a deposit of magnetite, located about seven miles from the mouth of the Pitt River, in Shasta County, California. This ore is a very pure magnetite, having on an average the following percentage composition:

Fe	69.90
MgO	0.10
MnO	0.18

¹For account of the work done in this type of furnace in California, see this Journal, December, 1911, page 631.

cent article by R. W. Van Norden on "Electric Iron Smelting at Heroult, Cal."

The furnace is housed in a heavy steel frame building, covered with corrugated-galvanized iron. It is rectangular in shape, 120 ft. long and 75 ft. wide, and has a height of about 60 ft. The building is in two sections or bays divided by a line of columns. The more southerly of these is the pouring floor, on which the pigs are cast. Throughout this bay is

FIG. 3.—VIEW OF ELECTRIC IRON REDUCTION FURNACE AT HEROULT, CAL.

operated a 50-ft. Northern Engineering Company traveling crane. This is electrically operated and has two hoists, one of 20 and the other of 5-ton capacity. A Cleveland Electric Controller & Manufacturing Company lifting magnet, having a capacity of 2000 lb., is used in picking up the pigs. This magnet will lift about 1000 lb. of hot pigs.

The bay to the north of the center columns is given to the electric furnaces, their transformers and the necessary control. While but one furnace, having a capacity of 18 tons of pig iron per twenty-four hours is at present in use, two more of slightly greater capacity are practically completed. There is space reserved, and it is intended to immediately construct three more, thus bringing the total number of furnaces in this building to six.

The Furnace.

The crucible is contained in a steel shell 27 ft. long, 13 ft. wide and 12 ft. high. The shell is so lined with refractories that the upper half of the box is rectangular, but in the lower half the sides taper toward the center of the foundation, and the ends slope toward the middle to facilitate the flow of the molten bath, when the furnace is tapped. The tap hole is in the center and front of the crucible. The roof of the furnace is arched, and opening into the same are five stacks through which the charge is conducted into the crucible. In the four spaces between the stacks at the center of the dividing arches are inserted the graphite electrodes. The electrode jackets and the arched roof are water-cooled. The stacks or pipes through which the ore is charged are 24 in. in diameter and extend upward to a distance of 15 ft. from the roof of the crucible. These stacks are used only for the purpose of charging, no reduction being attempted in them. A charging platform is built along the top of the stacks and carries a track which runs to the mixing platform. Dump cars with the charge are run on the charging platform and dumped directly into the stacks. Except when receiving a charge, the stacks are closed with a tight-fitting cap.

The Electrodes.

Graphite electrodes are used. They are cylindrical in form, 12 in. in diameter and 4 ft. long. The upper end has a tapered male-threaded nipple, while the lower end has a corresponding socket with a female thread. As the electrode is fed into the charge a new one may be fastened to it, making a continuous feed.

An electrode lasts in continuous operation thirty days. Occasionally an electrode breaks in the furnace. This was formerly a serious matter and caused considerable delay and annoyance in the operation of the furnace. It was hard to determine just where the break had occurred, although it was generally at the threaded joint. A novel means has been devised by which the furnace men are now able to ascertain whether an electrode is broken or not. A bar is driven into the furnace opposite the electrode, through one of the several peep holes, and at the same time the electrode is tapped on top with a hammer. The man on the bar simply listens for the tapping. The tapping is then done on the bar and the man on the top listens. A break may be accurately located in this manner.

Transformers.

In the rear of each furnace, and as close thereto as is possible, are the three service transformers which supply three-phase current at from 40 to 80 volts to the electrodes. These transformers are oil-immersed and water-cooled and have a capacity each of 750 kw. The low-tension connections to the electrodes consist of eight pieces of flat copper bar, $\frac{3}{8}$ in. thick and 5 in. wide, bolted together. On the 2400-volt primary side there are brought out eight current taps for voltage regulation.

These are taken to an oil-immersed, individual solenoid-operated switch group, which, with auto-transformer compensator, gives fifteen steps for voltage variation.

Electric Control.

Electric control is through a switchboard, there being a panel for each furnace. As the current and power-factor in each phase must be under observation at all times during operation, separate meters are installed in each phase. The requirements for one panel are three ammeters, three voltmeters, three wattmeters, three power-factor meters and three recording wattmeters. These are mounted across the panel in rows of three each. Under the first four sets named are three hand wheels to control the voltage variation, and under these three switches, which control the entire load, and still under these are the recording wattmeters.

For operating the voltage control and the main circuit breakers there is a 7½-kw. motor-generator set, comprising a 125-volt direct-current generator, directly connected to a 10-hp induction motor. This set has a small panelboard mounting a circuit breaker, ammeter, voltmeter, and two single-pole knife switches. The transformers, switches, and control were supplied by the General Electric Company. In the event that line voltage should fall, or for any other cause, the direct-current supply should become deranged there is a National Storage Battery Company's set, having a capacity of 7½ kw, which may be instantly switched in, and thus prevent the furnaces from cutting out in the case of low voltage.

*Reprint from Journal of Electricity, Power and Gas, Nov. 23, 1912.

Operation.

In operation the furnace is continuous. After a period of eight hours the hearth contains a full bath of molten metal, and this is, therefore, tapped three times each day. Charging is done at regular intervals and the current is not shut off at any time.

During the period of smelting the change in electrical conditions is interesting. At the beginning of the charge the power-factor is almost unity. This gradually lowers as smelting continues, until with a full bath of metal a power-factor of about 5 per cent is reached. If coke is used in place of charcoal, or if a mixture is employed a different set of power-factor conditions exists. By studying these conditions it is possible to know the exact condition of the charge by looking at the meters. The load is, of course, a function of the voltage, and with half voltage the load will drop one-quarter.

In charging, the ore cars are run on the mixing floor, which is at the same level as the charging floor. Cars with charcoal come into the lower part of the building and are hoisted on an electrically operated elevator to the mixing floor. Lime and quartz for flux are also brought in in cars, and each material is dumped into bins. The mixing is done in a car which is run on a platform scales. The charge is placed in layers, the proportions depending upon the tests made in the laboratory by the chemist. Following is a representative charge:

- 500 lb. iron ore (magnetite);
- 135 lb. to 150 lb. charcoal;
- 3¼ lb. lime (well burned);
- 12½ lb. quartz.

Comparison of the California and Swedish Furnace and Process.

As to the construction of the two types of furnaces, the difference is so apparent that no comment is necessary. As to the process, the California practice differs from the Swedish practice very decidedly in the following respects, namely:

1. No attempt at reduction in the stacks of the furnace.
2. Non-circulation of gases.
3. The use of limestone calcined outside the furnace.

In other words, the California practice is just the reverse of the Swedish practice, for in the latter they attempt reduction of the ore in the shaft of the furnace, they circulate a part of the gases escaping from the top of the shaft, and they do not use burned limestone.

Reduction in Shaft.

It would seem that the ideal condition in electric reduction furnace work would be to have the charge in such a condition as to only require melting by the time it comes in proximity to the electrodes. If this be done, the electric current is then only called upon to furnish the additional heat necessary to bring about the melting of the hot, previously reduced oxide. Of course, the heat for the reduction must come from some source, and its origin would be in the crucible and as a result of the heat developed during the melting of the charge, but, as will be stated presently, the excess heat so developed can be transferred by the circulation of the gas to the charge in the shaft and not carried away by radiation and an excessive amount of cooling water.

Gas Circulation.

In the Swedish practice, a portion of the gases rising from the top of the shaft are returned to the crucible and made to pass through the same and up through the charge in the shaft. This is done for the following reasons:

1. To cool the superheated brickwork.
2. To carry up through the stack a sufficiently large volume of gas which has been raised to a high enough temperature to bring about reduction in the stack.

As has been previously pointed out in this article, one of the most serious difficulties that had to be overcome in the development of the Swedish type of furnace was the destruction of the crucible due to local heating in the vicinity of the electrodes. Therefore by returning to the crucible a portion

of the gases resulting from the reduction of the ore, it is possible to prevent excessive local heating and at the same time to make use of the heat instead of wasting it. This matter has been the subject of much discussion, and has its objections, but the writer is of the opinion that its advantages in the way of economy of operation far outweigh its disadvantages. Perhaps it will in time be found practical not to use gas circulation in the electric iron reduction furnace, but, on the other hand, we believe that reduction previous to melting will be considered the proper practice, which means stack reduction, and the present California practice will not find application except in those instances where the local conditions warrant the same, as is the case at present. As has been pointed out, the present demand in California is for a soft grey foundry iron. The furnace now used gives that product, but this does not mean that such a construction and such a process are absolutely necessary for the production of such an iron. As a matter of fact, many tons of the same kind of iron were made at Heroult in a furnace of the Swedish type, and the Swedish inventors claim that it is possible to operate their type of furnace so as to reduce regularly an iron of the same character as is now produced at Heroult. They state, however, that in operating the furnace for this purpose the amount of electrical energy consumed per ton of pig produced is increased.

As to why the California type of furnace is better suited to the production of a soft grey foundry iron than is the Swedish type of furnace, it is probably due to the fact that reduction is performed solely by solid carbon in the crucible and as silicon is only reduced by solid carbon, its reduction to silicon takes place at the same time as that of iron oxide to metallic iron. The silicon is dissolved in the iron and by its presence causes the carbon to precipitate out as graphitic carbon, and there is thus obtained the soft grey iron desired. We are also of the opinion that in a furnace having a rectangular-shaped crucible, such as has the California furnace, the temperature of the charge in the crucible as a whole is much higher than is the case in a furnace of the Swedish type, and this higher temperature is more favorable to the reduction of silica to silicon, the latter, as before stated, being largely the controlling element in the production of soft grey foundry iron.

The Use of Calcined Limestone.

This has been repeatedly suggested, and theoretically it is the proper thing to do, but when operating a furnace of the Swedish type there are two objections to its use, namely:

1. It increases the percentage of fines in the charge.
2. It makes the charge hang.

As to the former of these objections, the idea seems to be more or less prevalent that there is no limit to the percentage of fines that may be used in the electric reduction furnace. We are not definitely informed in regard to this point with reference to the California practice, but judging from observations made upon the smelting of black sands, when the furnace consisted simply of a crucible and no shaft, more or less difficulty was experienced on account of the charge being made up entirely of fines. In the Swedish practice, the matter of the proportion of fines that can be used in a charge was definitely determined in the work at Trollhättan, and it was found that a large proportion of fines was detrimental to smooth running and good results, but Mr. Leffler, one of the engineers in charge of the work at Trollhättan, states that he is of the opinion that calcined limestone may be advantageously added to the charge if no reduction is attempted in the shaft.

Summarized, then, we may say that the California practice as compared to the Swedish practice presents the following advantages:

1. Permits the use of limestone calcined outside the furnace.
2. Does not require the circulation of gases.

As to this latter point, and also as to reduction in the shaft, we are not sure but what the California practice would prove more efficient if both were done. Although a very full and

¹"Gas Circulation in Electrical Reduction Furnaces," J. W. Richards, Transactions, American Electrochemical Society, Vol. XXI, page 403.

complete record of the working of the furnace at Trollhättan has been published, such is not the case as regards the operation of the furnace at Heroult, and so it will not be possible to make a definite comparison of the two practices until it is possible to receive as definite information in regard to the working of the furnace at Heroult as is now available in regard to the operation of the furnace at Trollhättan.

Lines Along Which the Electric Furnace Will Probably Be Improved.

The Size of the Unit.—In Scandinavia the furnace has gradually been increased in size until now there are 3000-hp furnaces in operation and A. B. Elektrometall have completed a design for a 7500-kw furnace. Naturally the problem in connection with a furnace of the Swedish type is to get such an arrangement of the electrodes as to insure a practical uniform heating of the whole contents of the crucible, and at the same time maintain the electrical equilibrium of the power system.

It is quite certain that the Swedish type of furnace will be improved along this line, namely, increase in size of the unit, and it is for this reason that results obtained from the operation of a furnace designed for 7500 kw will be awaited with great interest.

As for the California type of furnace, it will no doubt be possible to indefinitely increase the length of the same, just as has been done with the modern rectangular copper blast furnaces.

Efficiency.

The efficiency of the furnace will also be increased as time goes on, and probably by improvements along the following lines:

- (a) The utilization of the waste gases.
- (b) The securing of a high power-factor.
- (c) The correction of induction losses.
- (d) The further study of the single-phase furnace vs. the three-phase furnace.

As regards the latter, inasmuch as practically all large power installations are three-phase, it would seem that the only logical thing to do is to use three-phase current in electric furnace work, but from data submitted by Catania it would seem as if the mono-phase furnace is more efficient than the poly-phase furnace.

Summary.

Summarized then, we may say that the electric iron reduction furnace has passed the experimental stage; that it is meeting the requirements in those localities where it has been introduced, and that it will no doubt find extended application in those countries where the conditions are favorable to its introduction, namely, where electric power is comparatively cheap and where coke and charcoal are comparatively high. Inasmuch as the cost of electric power is largely the governing factor in determining its adoption, and as the cost of electric power is constantly decreasing, we may expect to find an extended application of the electric reduction furnace in the future.

Pittsburgh, Pa.

Bakelite Billiard Balls.—Another milestone has been reached in the victorious course of bakelite in its introduction into the most varied industries by the invention of the bakelite billiard ball. Ivory lacks uniformity and is seriously affected by changes in temperature and climate. As a result of years of scientific experiment a composition ball has now been perfected which is of the same weight and resiliency as the best ivory ball, but practically indestructible and absolutely unaffected by heat or cold, dryness or dampness. This composition ball is the invention of Mr. J. W. Hyatt (the inventor of celluloid) in co-operation with Mr. Charles F. Burroughs. The basic material of this ball is bakelite, Dr. L. H. Baekeland's well known invention. The bakelite ball is made by the Hyatt-Burroughs Billiard Ball Company, 141 Commerce street, Newark, N. J.

The Billiter Alkali-Chlorine Cells.¹

By A. J. Allmand, D.Sc.

The most important advances made in late years in the technical electrolysis of alkaline chlorides for the production of caustic alkali and chlorine are perhaps due to Dr. Jean Billiter, privatdozent in the University of Vienna. Some years back he designed a diaphragm cell which is being exploited by Siemens & Halske, and recently he has invented a modified form of the well-known bell-jar cell, which is undoubtedly, taken all in all, one of the most efficient cells now operated technically. The Billiter-Siemens diaphragm cell I propose to mention briefly only, as full accounts of it are available elsewhere,² and shall devote most attention to the Billiter "membrane" cell, the first installation of which started work early this year.

Billiter-Siemens Cell.

Most diaphragm cells in technical use have vertical diaphragms (e. g., Hargreaves-Bird, Townsend, Finlay). Billiter however, has returned to the use of horizontal diaphragms such as were formerly employed by Le Sueur and by Carmichael. He has compared elsewhere the relative advantages and disadvantages of the vertical and horizontal arrangements.

A horizontal diaphragm is more slowly attacked chemically, as it remains more or less saturated with the alkali which migrates upwards from the cathode situated immediately underneath. This is particularly important when making strong alkaline liquors. Further, the hydrostatic pressure on it is uniform at all points, not varying with the height as in vertical diaphragms. This means a more uniform flow of liquid through, and consequently a more efficient checking of the movement of the OH⁻ ions towards the anode.

There are corresponding structural disadvantages. The floor-space needed is greater. Further, the insides of the cells are less easily accessible and the anodes are necessarily of more complicated construction.

The active diaphragm material in the Billiter-Siemens cell consists of a mixture of asbestos wool and BaSO₄, spread out evenly on top of a sheet of woven asbestos cloth, which in its turn rests on the iron-wire net-work which constitutes the cathode. The function of the asbestos cloth is merely to support the BaSO₄ mixture and to prevent its being displaced by the lively hydrogen evolution. The cathode makes contact with the iron bottom of a trough, the sides of which are lined with cement, and the anode chamber is formed by a non-conducting bell-jar which is securely cemented around the edges of the diaphragm. An important feature of the cell is the arrangement for heating the electrolyte by means of earthenware pipes through which hot liquids run, these being immersed in the brine at the top of the bell-jars.

Cells have been made carrying up to 3,000 amperes at a current density of 4-6 amp. per sq. dm. Working at 85-90 deg., 12-16 per cent. NaOH or 18-20 per cent KOH can be made at a 95 per cent cathodic current efficiency, employing 3.5 volts.

An interesting laboratory study of the Billiter-Siemens cell has been recently published by Mühlhaus.³ He finds that the BaSO₄ used for the diaphragm is best precipitated hot. No change of size of grain when in the hot liquors of the Billiter cell is then likely to take place, and a regular and uniform liquid flow is thus assured.

The highest current density permissible is about 6-7 amp. per sq. dm.

Above this limit, disintegration sets in. Using 30-32 per cent brine at ordinary temperatures, the following figures were obtained

¹A paper read before the Faraday Society in London on November 26, 1912.

³Dissertation (Dresden, 1911).

Concentration of Alkali.	Current Efficiency. Per Cent.
3n.	98-99
4n.	95-97
5n.	80-85
6n.	75

The chlorine gas fell in purity from 99.5 per cent to 92 per cent as the alkali concentration was increased. The oxygen produced exceeded the amount of CO_2 . The solid caustic resulting contained considerable quantities of NaClO_3 if produced from liquors stronger than 4n. The best results on the whole were given when making 4n. NaOH at a current density of 4 amp. per sq. dm. Raising the working temperature to 70-80 deg. improved both energy efficiency and purity of alkali.

The Billiter-Siemens process is now operated as follows:

(a) In Aschersleben, Saxony, by the Kaliwerke Aschersleben A.G. Ten 2,000-ampere units.

(b) In Höchst, by the Farbwerke Höchst.

(c) In Brückl, Bosnia, by the Bosnische Elektrizitäts A.G. Sixty-four 2,500-ampere units.

(d) In Krumau, Bohemia, by Ignaz Spiro und Söhne. Thirty-two 500-ampere units.

(e) At Niagara Falls, by the Niagara Alkali Company. A 1,000-kw installation of 3,000-ampere units.

A number of plants are also being installed or enlarged. The Niagara Alkali Company (which has succeeded the old Roberts Chemical Company), is at present increasing the size of its plant from 1,000 to 3,000 kw. It has also been made known that a new factory for caustic alkali and bleach is being erected, commencing with 78 2,000-ampere units, and that a textile factory is installing 24 100-ampere units.

Billiter-Leykam Cell.

In this cell⁴ Billiter has successfully modified the bell-jar process, placing the cathodes (hooded to collect the hydrogen) immediately underneath the bell-jar, and not around its sides, as in the Aussig cell. Similar constructions had been formerly suggested by Richardson⁵ and by Bein,⁶ but had achieved no technical success.

By doing this, Billiter gains an important advantage. In the ordinary bell-jar cell, both flow of liquid and flow of current change in direction at the lower edge of the bell-jar. This results in non-uniformity of current density and liquid flow in the different parts of the bell-jar section. At some points liquid will be flowing more quickly than is necessary to overcome the OH^- migration towards the anode, at other points the contrary will be true; the movement of the OH^- ions will predominate, and the current efficiency will fall. This last statement particularly holds for those parts of the bell-jar section furthest removed from the walls, where the current of liquid is exceedingly slow. The larger the bell-jar, the greater proportionately is this disturbance. It also increases rapidly with current density. The consequence is that the units (bell-jars) at Aussig are very small, and can only be worked at a low current density, furnishing weak alkali. Such a plant requires much floor space for its output and the labor charges are high.

In the Billiter cell, this change of direction and the resulting irregularities are avoided, the motion of the brine being directly opposed to that of the current lines until it has passed the cathodes. The consequence is that high current densities can be used, stronger caustic liquors produced, high current efficiencies obtained, and large units constructed. At the same time, the advantage of the bell-jar cell—the absence of diaphragms—is essentially retained. For though the current must all pass through the hoods which cover the cathodes, this is not true of the electrolyte. Most of it passes directly through the space between neighboring cathodes, and is charged with caustic by diffusion from the concentrated alkali which fills

the cathode hoods. Not only does this alkali protect the hood material (in practice, woven asbestos) against chemical action of chlorine compounds, but suspended matter present in the brine is not filtered out, as happens in diaphragm cells, and it is not necessary to purify the brine in any way. The asbestos hoods are made of as coarse a structure as is consistent with their function of leading off the hydrogen gas, and affect the voltage to a very slight degree only. Finally, the cell is heated in a similar fashion to the Billiter-Siemens cell, and the voltage thus lowered.

The essential parts of the Billiter-Leykam cell are shown diagrammatically in Figs. 1 and 2. A is the bell-jar inverted in the cement trough B, and provided with anode outlet for chlorine, inlet for brine and heating arrangement (not shown). The cathodes C are arranged below the bottom level of A and consist in practice of T-iron. They are enclosed separately in long woven asbestos tubes which are suitably braced in order to avoid deformation by the evolved hydrogen, and are slanted sufficiently to allow the gas to stream away readily. These cathodes project out into a side compartment of the cell as shown, from which the hydrogen can, if necessary, be collected.

The causticised brine flows off through D.

The Austrian rights to the Billiter bell-jar cell have been purchased by the paper manufacturers Leykam-Josefsthal A.G. The first plant has been erected in their factory at Gratwein, a village on the Austrian Southern Railway, a few miles from Graz, has been in continued operation since early 1912, and has given every satisfaction. Some 1,700 to 1,800 kilos of active chlorine are produced daily, and the whole plant uses about 400 P. S.—350 P. S. for the cells and 50 P. S. for auxiliary pumps, fan, etc. Power is purchased from a company at 150 kr. (\$31.25) per P. S. year. After converting into direct current, and reckoning all losses in leads, etc., the cost comes to 180 kr. (\$37.50) per P. S. year.

The plant consists of 561,200-ampere units, 50 of which were working at the time of my visit last July. The cells are 5'5 metres long, 1'1 metres broad (internal measurements), and about 1'3 metres high. The side walls commence to slope inwards about 70 cm. below the top of the cell. They are built of reinforced concrete, the upper part being lined with earthenware bricks set in cement.

They are provided with three cement lids, each of which cement lids, each of which carries eight anodes.

The anodes are of Acheson graphite (1'0 x 0'18 x 0'05 metre), each being led through its lead by means of two graphite rods. The lids are cemented on to a shallow shelf cut out of the wall of the cell by means of ordinary putty, which stands the action of chlorine very well and always remains fairly soft. Putty is also used at the points where the anodes pass through the lids, as the weight of the anodes is not borne by the latter, but by the copper leads above. Each anode takes 50 amperes at a current density, assuming lower and side surfaces to be active, of about 1'6-1'7 amp. per sq. dm.

The cathodes are of T-iron and enclosed in woven asbestos tubes. These taper down slightly towards their closed lower ends, and the whole is braced by the insertion of a wedge-shaped strip of asbestos cement. The tubes pass through holes in the dividing wall into the side compartment of the cell as indicated in Fig. 1. Two iron rods attached to each T-iron cathode take the current to the copper leads above. The hydrogen is allowed to escape. The cathodes are, of course, about 1 metre in length, and the mean breadth of the asbestos tubes is about 5 cm. Between each tube there is a space of 5 to 8 mm. The upward slope of these tubes is about 2 cm. per metre.

The brine (moving from a reservoir under gravity) is led to a distributing box situated above the cell. From this it proceeds by way of a series of short capillary tubes (1.5 mm. bore) to 22-in. tubes, which pass through the cell lids, and is

⁴British Patent, 11,693 (1910), *Proceedings of Applied Electrochemistry*, 373.

⁵British Patent, 5,694 (1893).

⁶Chem. Abstr., 7, 18 (1895).

⁷The P. S. (Horse Power or German Horse Power) and P. S. year are of course about 1/3 per cent. smaller than the corresponding H. P. and H. P. year units.

thus fed in between the anodes. Regulation of the main supply to the cell is effected by means of a rubber tube and clip. This arrangement acts on the whole very satisfactorily, though the capillaries sometimes get stopped up. The causticised brine is drawn off from one side of the cell by means of siphon overflows. Three are provided, but one only is used in practice.

The heating arrangement used by Dr. Billiter in his diaphragm cell, though available for all other installations of his "membrane" cell, cannot be used at Gratwein. The cells are, therefore, provided with a heating arrangement which employs steam, the details of which, however, I cannot divulge here. When I was at Gratwein the cells were being mostly worked at room temperature, whilst those few which were being heated were working at 65 deg. to 70 deg. The cost of the steam used is very small.

The cells are arranged in four rows, two rows being worked in series, and are insulated by glass resting on concrete supports. Beneath the cells are arranged the chlorine and brine pipes, and a channel for the caustic liquors. The chlorine pipe-line is constructed of cement, junctions being made by covering the ends with a cement box and filling up with as-

FIG. 1.—SECTION OF BILLITER-LEYKAM CELL

phalt. The current leads are of copper, those connecting the cells of circular cross-section and 3 cm. in diameter. They are all painted with a composition stable against chlorine and acid fumes, as are also the tin tubes and rubber connections referred to above. The cells are worked under slightly reduced pressure ($\frac{1}{2}$ cm. of water), and, as a matter of fact, no smell of chlorine was noticeable. Ventilation can be effected, if necessary, by blowing air in through the agency of a fan driven by a horse-power motor. A traveling-crane is provided to facilitate lifting off the tops of cells, etc.

Saturated brine is used, prepared in the simplest way. A long cement trough is filled with large lumps (20-40 cm.) of crude salt. Water enters continuously at one end, and saturated brine leaves at the other. It is not purified, and can be sent straight to the cells. The average cathode liquors produced contain 12-13 per cent NaOH and about 20 per cent NaCl. By decreasing the rate of flow of brine, 16 per cent NaOH can readily be made. Up to 350 litres of brine per cell are causticised in 24 hours. The liquors are first evaporated in two vacuum pans, furnished by the Skodawerke A.G., Pilsen, and similar to those used in sugar refineries. In these they are successively brought to 30 deg. and 40 deg. B. Then by means of a Kaufmann rapid evaporator they are brought to 50 deg. B before going to the melting-house. The final product, which will probably be later somewhat improved upon, contains 97 per cent NaOH, 1.2 per cent Na_2CO_3 , and 1.8 per cent NaCl. The chlorine is diluted and absorbed in milk of lime.

Cells which are worked at room temperature take about 4 volts. Those I saw working at 65-70 deg. require 3.4-3.5 volts. Long continued experiments carried out with a 250-ampere unit have shown that at the normal working temperature of 85 deg. the voltage falls to 3.1 volts (*plus* in all cases the voltage drop in the leads). The cathodic current efficiency is about 92 per cent for 3n-4n alkali.

It remains to be added that wear and tear in the cells are very small. Under normal working conditions the anodes lose about 1 mm. in thickness at their bottoms and sides in two months. Suspended matter in the brine settles on the bottom of the cells, and the asbestos hoods remain unaffected. Finally, when once matters are adjusted, the whole system works automatically. The actual cell-room in Gratwein is worked by shifts of one workman only, whose duty it is to adjust the rates of flow in the different cells. Moderate fluctuations in rate of flow of brine or in current density result in a change in the alkalinity of the liquors produced, and in a corresponding *small* change in current efficiency. The cells at Gratwein work at a current density between the electrodes of about 2 amp. per sq. dm. only. With cells working at 85 deg. the most convenient figure, according to Billiter, is 4 to 6 amp. per sq. dm.; but, by suitably varying the other conditions, 14 amp. per sq. dm. can be employed.

The withdrawal of 350 litres of catholyte per cell per 24 hours corresponds to a movement of the brine of about 0.0007 cm. per second. The OH' ions in that part of the catholyte between the electrodes will have a velocity anodewards of just about the same magnitude. (E.g., assuming the cell to work at room temperature, the conductivity of the electrolyte would be about 0.5 recip. ohm per cu. cm., the velocity of the OH' ion at a voltage gradient of 1 volt per cm., 0.0018 cm. per sec., and the actual velocity $0.02 \times 0.0018 = 0.5 = 0.00072$ cm. per sec. This close approximation between the two opposing velocities, with the consequent straying of OH' ions towards the anode, is of course the chief cause of the 8 per cent deficiency in cur-

FIG. 2.—SECTION OF BILLITER-LEYKAM CELL.

rent efficiency, as the amount of chlorine which dissolves in the concentrated brine, and which would thus tend to be carried to the cathode, is very small.

The second installation of the Billiter membrane cell is at the present time being erected in Saxony.

In conclusion, I will again emphasize the chief characteristics of the Billiter-Leykam cell. They are—

- (1) Freedom from diaphragm troubles.
- (2) Use of impure brine.
- (3) Automatic working, great adaptability, and low attendance charges.
- (4) Alkali (3n-4n) strong compared with most other non-mercury cells.
- (5) With heated cells, lowest energy consumption per ton of product of any of the electrolytic cells now working on a large scale.

*The patent rights are not there available.

Concentration of Scheelite.

There is but one commercially important deposit of scheelite in Canada. It lies in the central part of Halifax county, Nova Scotia, 12 miles from the Atlantic coast and 34 miles from the nearest railroad point. It is 2 miles west of the old Moose River gold mines. The ore consists of quartz, scheelite, ankerite and arsenopyrite. Not a particle of either of the black tungsten ores¹ has ever been found with the scheelite. In a paper read before the Colorado Scientific Society by Victor G. Hills, the method of concentrating this ore is described, as follows:

Construction and Operation of Mill.

On March 1, 1911, I took charge of the property to develop the mines and build a mill. Foundations for boilers and air-compressor were begun by blasting in frozen ground. The lumber for building was made with a portable saw-mill from trees cut in the nearby woods. There was neither clay nor sand for brick, mortar, or concrete. Brick was hauled in on sleighs at a cost of \$30 per thousand; also some sand was hauled 18 miles by sleighs. Later, when the river was clear of ice, sand was made out of quartzite boulders by crushing in an old water-power gold stamp-mill found 2 miles distant. A wagon road had to be built into the camp when the ground was thawed out enough to permit it. The best English Portland cement and Scotch fire-brick were readily obtainable at Halifax, but the 34 mile wagon haul for these things and for the machinery made construction tedious and slow, and the year 1911 was consumed before the mill began producing concentrate.

A modest but substantial mill was built to treat one ton of crude ore per hour. I outlined a flow-sheet to take advantage of every inexpensive device to prevent sliming. The ore was dumped over a grizzly before going to the crusher. The roll feed was washed by a spray so that only the clean coarse material went to the coarse rolls. Rolls were used for crushing, as being undoubtedly better than stamps or any other form of screen-faced pulverizing mill to avoid sliming.

While the scheelite is more friable than either the quartz or the ankerite and, as usual in the concentration of all tungsten ores, the main loss is in the slime tailing, yet this loss with scheelite is somewhat less than with our Colorado black ores. The walls of the vein are slate which makes an enormous amount of slime and augments the difficulties of handling this portion of the pulp. This must be remembered when considering the loss in slime tailing.

In milling, since scheelite and mispickel have the same specific gravity—6.0—they together form the concentrate from the tables. The pyrite is just enough lighter to enable it, for the most part, to be thrown out with the tailing.

The raw concentrate consists of some 45 per cent mispickel coming partly from the vein and partly from the slate wall-rock. To get rid of the arsenic it was necessary to roast and treat with a magnetic separator. This phase of tungsten milling, of course, does not appear in our Colorado work.

Roasting for Magnetic Separation.

For roasting a Wilfley revolving hearth furnace was built. It proved quite satisfactory. For treating separately numerous small lots of both coarse and fine material, and particularly where the furnace can not be kept in steady operation, I know of no roaster that would be more desirable. The literature on the subject of ore-roasting seems to be notoriously meager in reference to the degree of heat used in connection with the time of exposure. I found that this mispickel was decidedly better prepared for the magnetic separator by a high temperature and short exposure. Thus, 1500 deg. F., for 50 seconds gave better results, for example, than 1100 deg. for 90 seconds. The tests which had been made on roasting this ore at the Kingston School of Mines had evidently proceeded on the idea of burning off as much of the arsenic as possible; but this idea was all wrong. The best separation of the arsenic can be made by the

least possible roasting that will render the iron magnetic. The arsenic can then be removed with the iron.

A Dings single-magnet separator made an excellent, clean separation. The magnetic part carried an average of 0.72 per cent WO_3 , with some lots as low as 0.42 per cent. The non-magnetic product carried only 0.34 per cent arsenic. And these returns could, if necessary, be further reduced by using a two magnet separator or by running through a second time. The separator operated at 8 amp.

The finished product carried, besides the 0.34 per cent arsenic, a little sulphur and phosphorus. Otherwise the concentrate contained no deleterious element. While no other tungsten ore in the world compares with our Colorado product for freedom from undesirable elements, this Nova Scotia product is quite within the general market requirements and compares favorably with the tungsten ores from most parts of the world.

With my trial run the mill saving was 86.8 per cent. Remembering that, besides the excessive amount of scaly slate gangue, augmenting the slime loss, this concentrate has to be subjected to a second loss from flue dust in roasting and a third loss from magnetic separation, I regard this as a good saving. The market product carried 70 per cent WO_3 . That this is higher than the average of our Boulder county product is, of course, due to the higher tungstic acid content of the lime tungstate. The coarser table products at Scheelite would run as high as 73 per cent WO_3 . A test on this ore made at the Kingston School of Mines reported a saving of 89.5 per cent; but the ore was sorted nearly free from slate and the method used was impracticable to apply in a small and simple mill. Additional mill equipment, introducing coarse jigs, regrading of middlings, and more slime-settling capacity, would materially increase the saving. It is the old mill problem; to determine whether the additional saving would pay for the outlay necessary to produce it.

Production of Copper and Nickel in the Electric Furnace.

At the first general meeting of the recently formed "Gesellschaft Deutscher Metallhütten und Bergleute" (Society of German Metallurgical Engineers, essentially restricted in its scope to non-ferrous metallurgy), Mr. M. Stephan gave an account of some experiments made by him on electric smelting in non-ferrous metallurgy. Mr. Stephan is the superintendent of the Girod electric steel works in Ugine, which are familiar to our readers from previous descriptions.

Copper.—Formerly the Keller-Lecloux Company, of Livet, France, have experimented with a Chilean copper sulfide ore containing 5.1 per cent Cu producing a matte of 40 per cent to 50 per cent Cu and a slag with 0.1 per cent Cu. The problem brought before the Society An. Electrometallurgique *Procédés Paul Girod* was to reduce a copper oxide ore in the electric furnace by means of solid carbon as reducing agent and with a certain limestone as flux.

The ore came from the Belgian Congo, being mined by a Belgian-English concern. In five different analyses given the CuO varies from 21.01 per cent to 5.73 per cent, SiO_2 from 28.48 per cent to 78.55 per cent, with from 4 to 13 per cent Al_2O_3 from 4 to 16 per cent Fe_2O_3 , and besides smaller impurities from 2 to 7 per cent CoO , no nickel.

The moisture in the ore varied from 7 per cent to 32 per cent. It was not removed in order to meet the conditions of practical operation and to carry the experiments out under most unfavorable conditions.

Charcoal, coke, and anthracite were used successfully as reducing agents. Charcoal will probably be the cheapest under the special circumstances. Electrodes were primarily carbons of Girod's own make, and also bottom electrodes of soft steel or water-cooled copper; 500 kw were available for the experiments, for which not over 200 kw were used at from 30 to 150 volts.

Ores of the kind described are difficult to work with in the

¹Milling practice on Colorado tungsten ores was described in this journal, July and August, 1911.

water-jacketed copper blast-furnace. They do not offer any trouble, however, in the electric furnace. Within the limits of the highly refractory furnace lining it is possible to regulate the temperature, viscosity and composition of the slag to suit any condition.

Electric furnaces similar to the Girod steel furnace type were used and dimensions changed in several runs within wide limits in order to secure enough data for the construction of a large furnace for the same work. Electrodes were used suspended from the top and inserted in the bottom, also in the sides for heating by radiation, and a system was adopted of heating with a smothered arc mainly by the resistance of a thick layer of slag over the conducting metallic charge. The temperatures were measured with LeChatelier, Wanner, and Fery pyrometers.

A slag of the composition

SiO ₂	Al ₂ O ₃	CaO	MgO	Fe ₂ O ₃	MnO	CuO	CoO
51.90	11.31	16.83	13.71	3.55	0.94	0.46	0.87

begins to melt at 1250 deg., begins to flow in a pasty condition at 1350 deg., and is liquid enough at 1400 deg. to allow the little copper balls to completely settle. At 1550 deg. the slag is liquid enough to flow off freely; 1920 deg. were necessary to render the slag liquid when the highly acid ore was smelted without any fluxes.

The pig copper (Schwarzkupfer) produced analyzed in six different runs from 65 per cent to 95 per cent Cu, containing from 1 to 21 per cent Fe and from 1 to 11 per cent Co. The purity of the product will be the higher the lower the melting temperature.

The lower the temperature the smaller will be the chance for reducing any of its impurities, but at the same time more copper will also be retained in the slag so that the output is decreased.

It will be a matter of commercial calculation, according to the composition of the ore and other special conditions, whether a high-quality product or a maximum output will be desirable.

A continuous run for several days with the same ore aiming at slags of about the above mentioned composition required 1000 to 1200 kilowatt hours per ton (of 2205 lbs.) of ore.

These figures are high, as a result of the amount of heat required to keep the very viscous and anomalous slags in liquid condition.

With an easily fluxible ore the specific power consumption was only about 500 kilowatt hours.

The electrode consumption averaged 8 kg. or 17.6 lbs. per ton of ore, using an electrode of 1.8 specific density and 3500 microhm resistivity (per sq. cm section and cm length); it was operated with 4 amperes per sq. cm (25.8 amperes per sq. inch).

Coal for reduction was used at the rate of 25 per cent of the copper in the charge.

The best lining to withstand the severe conditions of the furnace was tamped from fire-clay with 80 per cent SiO₂ and 15 per cent Al₂O₃.

Nickel.—While in older experiments of his firm and in the experiments described in the paper read by Walter Morrison before the American Electrochemical Society last year the product was a nickel with high Si contents. Mr. Stephan was able to obtain a ferro-nickel with only 3 per cent to 5 per cent Si, as for instance:

Ni	Fe	Si	Al	C	S
41.50	51.61	4.33	0.81	1.34	0.04 per cent

from an ore containing 8.33 per cent NiO. A small furnace of 220 kilowatt treated 3 tons of ore in 28 hours and produced 350 kg. of metal. From this the author concludes that on a commercial scale the specific power consumption would easily be reduced to 1200 kilowatt hours per ton of ore and that the electrothermic smelting of nickel ores will pay in districts when power is cheap.

The complete paper by Mr. Stephan may be found in *Metal and Erz*, vol. 10, pp. 11-17 and 84 to 86, 1912.

Wood Waste Utilization.

The Industry in Its Relation to Expert Advice

By John E. Teeple, Ph.D.

Here is an industry expanding and changing so rapidly that it is difficult to keep abreast of its progress. Every time I attempt a general review, its aspect has changed.

Processes and patents without number loom above the horizon. Most of them die without ever seeing the light of day in a commercial form, many never advancing beyond the paper and ink stage. Some start life hopefully, only to draw out a weary existence suffering from the disease known as "annual deficits." They approach so near death that when existence ceases and the scrap heap receives them we hardly notice the change.

A few, either sturdy by nature or well provided with nurses and doctors, live and grow to the mature form known as "dividend payers." These are rare, much rarer than need be if proper skill and experience were only called in at the birth of all. Like other infants their death rate is very high in the early period of existence. Fortunately, in this case, the doctor has no compunctions about letting an unpromising one die, or drowning it if need be for the good of the community.

The net results to date have been disappointing. The rewards have been few. The number of plants that have been on a real dividend paying basis for the last two years could be counted on the fingers of a one-armed man. On the other hand the crop of white hopes is large. The prospects of the industry as a whole were never better than they are to-day. A very respectable number of plants have recently started or are in process of construction. Most of these efforts show a very decided advance over those we have seen spring up in previous years.

In nearly every case, actual construction of the plant has been preceded by an investigation of the process by competent and experienced experts, and also by tests on a semi-commercial scale. Then there has been careful study of the type of raw material to be used, of the finished products and their marketability as judged by men who were thoroughly familiar with those markets, and finally an intelligent adaptation of the design and construction and location of the plant, both to the raw materials and to the finished products.

These may seem like too childish or self-evident precautions to receive special mention here, but it must be confessed that in the past, often many and sometimes all of them have been overlooked in constructing plants. Too often the process has been the whole thing. The man with a process and a long array of figures showing what wonderful products in amount and value he could get from a cord of wood, has frequently carried the investor by storm. Without waiting for the advice and experience of men who have spent years in the industry, as he would normally do in any other line, the investor plunged. There must be something fascinating about the industry, like there is about buying a mine, but nowadays even the mine buyers have an expert examination and report before buying.

A man with a process and a man with money sat at a mahogany desk. The process and the usual array of figures were there. The figures showed that from a cord of wood, kind and quality not specified, you could get wood alcohol, acetone, acetic acid, acetate of lime, turpentine, rosin, tar, pitch, oil of tar, creosote oil, sheep dip, disinfectant, wood preserver, cable coating, pine oil, liniments for man and beast and rheumatism, cough syrups, patent medicines, embalming fluids and gaulacol, and high-priced drugs of the pharmacopoeia.

Of course, it was all more or less true. The beauty of it is that you *can* get these, but the question is, do you want to? This particular investor did want to. He verified some of the prices from "Merck's index" and the "Oil, Paint and Drug Reporter" and added the long column of figures.

The fact that if you used up your raw material in making some of the products you couldn't have it left to make the others too, didn't occur to him. Further, he forgot that few of the products could be obtained from all woods, that some

would certainly be obtained from certain woods in an entirely unsalable condition, and others would cost more to make and refine in most cases than they could be sold for; still others would glut the market from one day's run of his plant, still others would probably be so different from standard articles, that their use would be restricted to special industries at much lower prices.

Overlooking all these things he followed a common practice of investors in arriving at a conclusion. He took the huge total of returns and deducted 50 per cent, then he deducted 50 per cent of the remainder. After providing this factor of safety, the total was still so large that it seemed certain a handsome profit would result no matter how it was handled. In fact, it seemed a shameful waste to use mahogany desks for office furniture when such rich returns could be obtained by distilling them. After the plant was built it was my painful duty to clear away the sad remains before it had produced a thousand gallons of anything or sold a cent's worth.

This was years ago, but I could cite many almost as bad in more recent years. There was a plant that ran intermittently almost a year without ever producing a single gallon of really marketable goods, and the men in charge did not know tar from pitch, and still no one was called in during that whole period to advise them.

There was another plant with a marketable process where the plant was designed and built complete, and only after the initial operation was started did they discover a glaring mechanical defect that made the plant as constructed, an impossibility.

There was a plant built to handle mill waste where the yields were small but a profit possible because the raw materials cost nothing, and then the whole was laid out so that every stick of wood had to be *handled twice by hand* before reaching the plant.

There was a plant constructed where raw material in the shape of lightwood was "countless as the stars," and investigation showed later that if lightwood of the kind desired was meant, the stars must have been counted on a very cloudy night.

But why continue the enumeration? It seems like a record of one case after another of useless waste. And we wonder about the high cost of living. Literally the amount unwisely expended in this industry amounts to millions. And it is not because we are lacking in competent chemical and engineering information and experience here. It is chiefly because the idea of the *process* has been overrated.

The man who can invent and think out a real idea suitable for a process has done his share. In nearly every other industry we realize that the type of mind capable of inventing is not the type most suitable for designing and constructing or managing a plant or for developing and criticizing his own process.

Why in this industry do we so magnify process and expect the inventor to be more superhuman than we do elsewhere? Why do we load him with the whole responsibility of success or failure instead of calling in the best man available to his assistance? And why do we invest in this industry on an interested man's mere word without calling in competent advice?

Within this present year I talked with an inventor anxious to interest capital in his process of recovering turpentine and rosin from wood. The conversation developed his supposition that no one else was doing this or had workable methods for doing it, and that the only thing he had to compete with was the destructive distilling type plant of thirty years ago. If the inventor, supposed to be expert in his subject, thinks this, why should we be surprised if he convinces the investor?

The process is one element of success; a good process is necessary, yes, but it is only one element, and there are many others. The character and cost of the raw material is most important and deserves an article by itself. The marketability of products has been overlooked again and again on the assumption that turpentine is turpentine and rosin is rosin. Sometimes they are, and sometimes they are not. The fact that John Jones sold his druggist a gallon of pine oil for ten dol-

lars doesn't give you a clue as to its price and consumption in tank car lots. If you read that light oil or heavy oil is quoted at fifteen cents per gallon, that does not indicate that you can sell light oil or heavy oil from white pine at that price, or necessarily at any price.

There is really just one way to determine the marketability and price of a product and that is to sell it or products identical with it on the open market. And then, as mentioned before, the location of plant as related to raw material and market, the design, construction and management should all be done in consultation with men who have been handling this same type of installation as chemists and engineers.

A frequent mistake lies in placing the problem before an analytical chemist. He may be an exceptionally good chemist, and may give accurate reports that will be entirely misleading through no fault of his own. I have before me now such a report on a process made by a thoroughly competent analytical chemist. The report so far as I can see was correct in all respects. Unfortunately, however, from lack of specific information which he could not be supposed to possess, the report indicated success to the chemist and to the investor. A single reading of it would have convinced a man experienced in the industry that nothing but failure lay ahead, unless many things were radically changed. The report actually led to one more useless expenditure of money.

It seems probable that nearly every possible error has been made at some place or time. Most of the mistakes could have been avoided if competent experts, of whom there are a sufficient number, had been kept in touch with the work from its inception. Unfortunately in many cases the man of training and experience in this particular industry has never been called in at all. In other cases he comes to give decent interment or shorten useless suffering. Why not call him in at the beginning, in time to announce to the proud father the arrival of a bouncing baby boy?

New York City.

Wet and Dry Grading.—In testing ore for a metallurgical process, dry screening will give erroneous results if the actual practice is to be wet screening or hydraulic classification. The test should conform to the proposed practice. The following table will illustrate the point. It shows the grades obtained by wet and dry screening an ore which was tested by Morris Green, who gives his results in the September *Journal* of the Chemical, Metallurgical and Mining Society, of South Africa. The ore evidently contains some material sufficiently brittle to be broken by the impact of dry screening.

Mesh.	Dry Grading.	Wet Grading.
—30	22.15%	25.7%
—30 —60	31.55	34.9
—60 —90	9.70	9.0
—90 —120	3.20	2.9
—120 —200	9.13	7.2
—200	24.27	5.2
Slime		15.1
	100.00%	100.0%

Flotation of molybdenum ore by the Minerals Separation process has given the following results: The ore assayed 1.82 per cent MoS_2 , from which by treatment in five successive units, a concentrate was obtained containing 92.08 per cent MoS_2 , with a recovery of 76 per cent of the molybdenum in the concentrate. The ratio of concentration was 100 to 1.66.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in September, 1912, was 63. The total quantity of ore milled during that period was 2,131,593 tons. There were 9970 stamps in operation, with an average duty of 8.36 tons per stamp per 24 hours. Tube-mills in commission numbered 273. The yield for the month was 747,893 fine ounces gold, which was slightly lower than for four preceding months. Fewer stamps and more tube-mills were in commission than at any time during the year.

Cyaniding Slimy Ore by Continuous Decantation

A review of the status of this important recent departure in cyanide practice, by H. C. Parmelee

THE early history of cyanidation is replete with instances of complete failure or great loss when treating ore which tended to form impermeable slime. Leachable sands were treated successfully by percolation, and in some instances it was possible to mix a portion of the slime with the sand and thus avoid a total loss of the precious metals contained therein. In other cases, however, it was temporarily more economical to discharge the slime and impound it against the time when some successful method of treatment should be devised. In this connection the revolutionary influence of agitation and vacuum filtration is a matter of common knowledge.

But great as was the effect of vacuum filtration in overcoming the obstacles in slime treatment, and important as it still is, and will be, in the cyanide industry, the more modern system of continuous decantation¹ is proving of almost equal importance in handling slime. The cyanide process is now the prevalent method of gold-ore treatment; and as the simplicity, economy and ease of operation of the continuous decantation system become better known, it is safe to predict its wider use. It has the advantage of low cost of installation and operation, and it can be combined with existing milling plants without great difficulty. In some instances it displaces filtration, other than clarifying; and where filters are used it permits the delivery of a low-grade pulp to the filter, thus minimizing the loss of dissolved gold in the filter tailing. It will be apparent, also, that the use of continuous decantation preceding filters will increase the capacity of a given plant of the latter by avoiding the time required for washing with barren solution. Eliminating this step would also decrease the cost of a filter-plant. Further, the operation of continuous decantation is simple and flexible, lending itself to a variety of conditions which may be reasonably ascertained in advance.

Continuous Decantation at Ophir.

A case in point is the recent cyanide practice at the remodeled mill of The Ophir Gold Mines, Milling & Power Company, Ophir, San Juan district, Colorado. The company is operating a group of mines, locally known as the Suffolk property, which has a record of production extending over 3 years, and aggregating over \$2,000,000 in value. Considering the situation of the property and the prevailing metallurgical methods it was natural that during the early years of its history, only high-grade ore was mined and milled. Recovery was effected al-

most wholly by amalgamation, with some concentration. The value of the ore treated ranged from \$15 to \$100, and the recovery probably did not exceed 60 per cent. Under the present system of cyaniding, without amalgamation or concentration, ore averaging \$3 gross value per ton can be mined and milled at a profit, with a recovery of over 90 per cent.

Nature of the Ore.

The Suffolk ore consists of quartz, decomposed porphyry and andesite, and contains gold to the value of from \$8 to \$12 per ton. Silver is found only in negligible quantities, and practically no other metals are present. Analyses show over 90 per cent insoluble. The ore is soft, a great deal of it being in the form of clean clay resulting from the decomposition of the porphyry. This condition readily explains the failure of former attempts at cyaniding by leaching. It also gives rise to much colloidal slime in the present system of treatment, but no difficulty is experienced in handling it.

Preliminary Experiments.

Preliminary experiments revealed certain ideal qualities for cyanidation not found in all ores. There are no reducing agents present and the ore is only slightly acid. Chemical consumption of cyanide is only 0.1 lb. per ton, and of lime 1 lb. per ton. Being soft, the ore is readily ground to slime. This is an important characteristic because the gold is very finely divided, and, after crushing, is found for the most part in the fine slime. Despite the fact that the ore contains a great deal of colloidal matter, and therefore does not settle readily, no difficulty has been experienced in handling it by the present method of continuous decantation.

An interesting feature disclosed in the tests was the fact that the quantity of readily soluble gold varied directly with the gross value of the ore, while the quantity of gold requiring time and agitation for its solution was almost constant regardless of the initial value of the ore. Thus it was found that

on all grades of ore the gold went into solution almost immediately to a point where the residues had a uniform value of \$2.40 per ton.

These residues yielded their gold on further agitation as is indicated in the time-solution curve shown in Fig. 1. From this it will be seen that solution goes on quite rapidly, giving residues containing twenty cents gold per ton after 36 hours agitation.

This is the standard now maintained in mill operation, although as a matter of fact "trace" tailings frequently are obtained.

FIG. 1.—SHOWING DECREASE IN GOLD CONTENT WITH INCREASED TIME AGITATION WITH CYANIDE SOLUTION. 1 LB. KCN AND 2 LB. CAO PER TON SOLUTION. TWO PARTS SOLUTION TO ONE OF ORE. LOSS KCN 0.1 LB. PER TON ORE. LOSS CAO 1.0 LB. PER TON ORE.

¹Articles relating to continuous decantation have appeared in this journal for July, 1911, pp. 365 and 373; Sept., 1911, pp. 436 and 439; Nov., 1911, p. 605; Jan., 1912, p. 27.

Crushing in Cyanide Solution.

The present milling system, based on many tests and calculations, is shown concisely in the flow-sheet, Fig. 2. In this connection it will be interesting to note that the results obtained in practice checked closely those indicated by the calculations. The flow-sheet shows the strength, value and tonnage of solution and pulp at different points in the process, so that it will be readily understood without much description. The figures are based on an assumed ore-value of \$5 per ton.

The milling process begins by crushing the ore in cyanide

FIG. 2.—FLOW SHEET OF OPHIR GOLD M. & P. CO.

solution with twenty 850-lb. stamps. The height of drop is from 6 to 7 in. at the rate of 104 drops per minute. With $\frac{3}{4}$ -in. screens on the mortars the twenty stamps have a capacity of 150 tons in 24 hours, and 30 per cent of the discharge will pass a 200-mesh screen.

Considering the nature of the ore, the stamping is not so much a problem of crushing as of disintegrating and washing out the clay.

The stamp product is separated into sand and slime in a Dorrl classifier, the sand being reground in an 8-ft. Hardinge conical mill. The latter carries a 4-ton charge of pebbles and runs at 31 r.p.m. Its discharge flows to an Abbe-Frienier pump which returns the pulp to the classifier. The classified slime is elevated by centrifugal pump to the first Dorrl thickener, 33 ft. diameter and 12 ft. deep, running at the rate of one revolution in 12 minutes. Solution of most of the gold occurs so rapidly in the stamp-mortar and tube-mill circuit that the overflow of this thickener is clarified and precipitated by zinc dust. The consumption of the zinc amounts to 0.15 lb. per ton of solution.

The rich solution is measured before precipitation, by means of an all-iron Worthington direct-displacement water-meter. An automatic sample is taken both before and after precipitation. The difference between the assay-value of these samples,

multiplied by the tonnage registered on the meter, gives the amount of gold precipitated during a given period.

Agitation.

The thickened slime, containing $1\frac{1}{2}$ parts solution to 1 of solids, flows to the agitators which are shown in Fig. 3 as they appeared before being enclosed in an addition to the old mill building. The agitators are of a new type, combining air and mechanical agitation, patented by Mr. J. V. N. Dorr. The mechanism is applicable to flat-bottom tanks of ordinary proportions; those at Ophir are of wood, 16 ft. high and 16 ft. diameter. The driving gear is supported on a frame-work at the top of the tank as shown. The central air-lift pipe is connected with the vertical driving shaft and revolves with it, being suspended in the tank. The open bottom of the central pipe reaches within 8 in. of the bottom of the tank and is directly above the inlet-valve for compressed air. Attached to the air-lift pipe near its lower end are the agitator arms to which are riveted angle-irons so placed as to draw pulp from the periphery to the center of the tank during the revolution of the mechanism. The arms are adapted to be lifted out of the pulp in case operation is discontinued for any length of time. The pulp discharged from the air-lift is directed into inclined radial launders attached to the top of the central pipe and revolving with it. The bottoms of the launders are perforated to distribute the discharge over the surface of the pulp.

In operation, therefore, there is a combination of air and mechanical agitation. The arms, which in this case revolve only once in 54 seconds, continually draw thickened slime from all parts of the tank and deliver it to the air-lift for circulation and agitation. This agitator is giving entire satisfaction. It avoids the inconvenience in mill construction due to the great height of Pachuca tanks, and it overcomes the difficulties arising from accumulation of sand, which frequently occurs in cone-bottom agitators.

It is recognized that in many types of agitators the intensity of agitation is determined more by the mechanical necessity of keeping the pulp in suspension rather than by the chemical requirements of the ore under treatment. This frequently results in a waste of power; and where air-agitation alone is used, the excess of air may readily be a disadvantage. This agitator

FIG. 3.—AGITATORS, OPHIR MILL.

maintains the pulp in suspension under every condition, and allows the intensity of agitation to be regulated to suit the needs of the ore.

Continuous Decantation.

The agitated pulp is subjected to a system of continuous decantation and counter-current dilution as outlined in the flow-sheet. The final tailing is discharged from the last thickener

without filtration. The loss in dissolved gold at this point is but three cents per ton, which compares favorably with similar loss from filters, the latter ranging from four cents up as high as twenty cents or more per ton. The discharged pulp contains from 48 per cent to 54 per cent solids. In applying this system, a vital thing to be observed is the point at which barren solution is added; and this is governed by the relative value of the pulp in cyanide and dissolved gold, and the proportion of each that may be most economically discharged in the final tailing.

It will be noticed here that in the present case the barren

FIG. 4.—PLAN OF MILL, OPHIR GOLD M., M. & P. COMPANY.

solution is added in the third of the five thickeners. This is based on experiments and calculations designed to give the lowest combined loss of cyanide and gold, and is not necessarily the exact scheme which would be followed with other ores and solutions.

By reference to the flow-sheet it will be seen that the flow of solution through the entire mill system is in a closed circuit, except for that portion of solution discharged as moisture in the final tailing. This is compensated by the addition of hot

water from the heating system, so that the solution is kept at an average temperature of 85 deg. F. The quantity of hot water thus introduced is governed by a float in the mill-solution storage tank, which operates a throttle valve in the hot water line.

The float is placed in this tank because it is the only one in the entire system in which the level of solution varies. It is also the only tank in the system besides the treatment tanks. Sump-tanks are not needed.

Air-Lifts for Transfer of Pulp.

An important feature at Ophir is the convenient arrangement and control of the air-lifts used for transferring pulp from one thickener to another. These lifts are similar to those used at Real del Monte, Pachuca, Mexico. The four thickeners are symmetrically arranged as shown in Figs. 4 and 5, and in the central space are grouped the air-lifts and boxes which receive the various pulps and solutions. This arrangement greatly facilitates inspection of the entire system of continuous decan-

FIG. 5.—SHOWING ARRANGEMENT OF THICKENERS IN CONTINUOUS DECAN- TATION DEPARTMENT. OLD MILL IN RIGHT BACKGROUND.

tation. The thick underflow discharged through a nozzle, and the overflow to be mixed with it, flow into a sump-box, and the mixture is elevated to the proper tank by an air-lift.

The construction of the air-lifts, of which there are three, is shown in the drawing, Fig. 6. The thickened pulp and diluting solution which are to be transferred to any one of the thickeners are received in one compartment of a box which is 2½ ft. square and 3 ft. deep. Attached to the bottom of each compartment, and extending downward into a concrete-lined well, is a 9-in. pipe, 23 ft. long, capped at the bottom. This gives a total submergence of 25 ft. below the normal level of slime maintained in the box. Inside the 9-in. pipe, and extending downward within 4 in. of its bottom cap, is a 5-in. pipe which rises also 13 ft. above the surface of the slime in the box and discharges the elevated pulp to the feed box of the desired thickener. The inner pipe is supported on legs resting on the cap of the outer pipe. A 1-in. compressed-air pipe is introduced into the top of the 5-in. pipe and extends downward within 10 in. of the bottom of the 5-in. pipe.

In each compartment of the box referred to is a float rigidly connected by an iron rod with a throttle valve on the air line. As the pump accumulates in any compartment, the float rises, opens the valve and operates the air-lift. When the level of slime in that compartment has been lowered, the float automatically closes the air valve and the elevation of pulp is temporarily discontinued. These pumps have proved effective in pulp transference and are economical in air consumption. They require little or no attention, and the only cost is for power.

Air is supplied at 30 lb. pressure, and under this condition the consumption of air is 30 cu. ft. per minute for the three lifts. In this connection it may be stated that throttle valves proved superior to butterfly valves, as the latter did not close as

tightly nor as quickly as the former, thus allowing an escape of air following each discharge of pulp.

In order to prevent the violent discharge of the air-lifts from agitating the settling pulp in the thickeners, a wooden float is placed in each feed-box to break the force of the incoming stream. The central feed-box is 3 ft. square and 5 ft. deep, dipping about $3\frac{1}{2}$ ft. below the surface of the pulp. The wooden float clears the sides of the box by a few inches and has a centrally-bored hole through which the driving shaft of the thickener passes.

Another system for transferring pulp may be noted here.

FIG. 6.—AIR-LIFT FOR TRANSFER OF PULP.

This consists in withdrawing the thick pulp by means of a diaphragm or other displacement pump set near the top of the tank. The pump discharge is then mixed with the proper overflow which flows by gravity from an adjoining tank.

This method gives closer regulation of the thickened discharge, as the withdrawal of the same volume in unit time means the delivery of more solid if the pulp becomes thick, and less as it becomes thin. The disadvantage of this system is the wear of diaphragms, which is partly compensated by the smaller power required.

Power, Labor and Sampling.

The property is favorably situated for the use of inexpensive water power, of which from 800 to 1000 hp. can be developed. At present two Pelton wheels are generating all the power required by the mill and the mine compressor. One 6-

ft. wheel with two $3\frac{3}{4}$ -in. nozzles is operating under a head of 100 ft., and one 3-ft. wheel with a 2-in. nozzle is running under a head of 375 ft. The mill is consuming about 110 hp. when treating 150 tons per day.

The labor normally required per shift in the mill is two men, with a repairman on the day shift, in addition to which there is a mill superintendent.

An automatic sampling system has been installed, controlled by a master-clock. The samplers are placed to receive the battery discharge, agitator discharge and final tailing from the last thickener. Samples are taken simultaneously for one second of time at half-hour intervals.

The work at this mill is worthy of note on account of the simple system of ore-treatment, which gives the best results at a low operating cost. The unit cost of installation, which in the last analysis must be distributed as an additional operating cost over the total tonnage to be treated, is considerably lower than would be the case for the usual filtration system.

We are indebted to Mr. George B. Pickett, general manager for the company, for permission to publish these data; and to Mr. Justin H. Haynes, general superintendent, and Mr. F. L. Veatch, mill superintendent, for supplying the details of the process as they have applied it to local conditions.

The Determination of Phosphorus in Vanadium Steels.

By E. W. Hagmaier.

The determination of phosphorus in the presence of vanadium has been a bugbear ever since vanadium steels have come into extensive use. The methods have either been long and tedious or not very reliable. The following method besides being short has proven accurate under all conditions in which it has been used:

The sample of steel is dissolved in aqua regia, taken to dryness and baked. When all the acid is driven off it is then taken up in strong hydrochloric acid; when complete solution is obtained the silica is filtered. The filtrate is then reduced with sulphurous acid. When entirely reduced 5 cubic centimeters of acetic acid 90 per cent and 10 cubic centimeters of cerium chloride saturated solution are added. Ammonium hydrate (about 1 part concentrated ammonia to 3 of water) is added drop by drop with constant stirring, until turbidity is shown. The solution is then heated to a boil, allowed to settle, and filtered. The cerium phosphate will filter rapidly, especially through a black ribbon paper. The precipitate is washed five or six times with hot water and then dissolved off the paper with hot (1-1) nitric acid, and the phosphorus precipitated as in other cases with ammonium molybdate.

Precautions:—It is better to filter off the silica before precipitating the cerium phosphate, for the presence of the silicon causes the cerium phosphate to filter slowly.

The point where most caution is required in the whole method is in adding the ammonium hydrate. This must be added very slowly, for if once too large an amount is added it seems impossible to obtain proper conditions by coming back again with hydrochloric acid. If by accident too much ammonium hydrate is added, the best plan is to filter the precipitate, redissolve it in hydrochloric acid, pass in sulphur dioxide, and reprecipitate the cerium phosphate.

This method has been tried with vanadium from 0.166 up to 5 per cent, and it has been found that in all cases above 0.5 to 1 per cent one reprecipitation of the cerium phosphate should be made, and with 1 per cent to 5 per cent vanadium two reprecipitations.

The following experiments were carried out by the above method, and in no case where the necessary precautions were taken did the ammonium phosphomolybdate precipitate show the orange color characteristic of vanadium contamination. The ammonium phosphomolybdate precipitation was also taken, redissolved and tested for vanadium, and no trace of vanadium was found.

In all of the following experiments the molybdate precipitate was filtered on a weighted paper and the phosphorus calculated using .0163 as the factor.

One gram of a steel having 0.60 phosphorus and 0.16 vanadium added. The following results were obtained: No. 1, 0.633 per cent P; No. 2, 0.596 per cent P; No. 3, 0.595 per cent P; No. 4, 0.614 per cent P.

One gram of steel having 0.60 per cent phosphorus and 0.767 per cent vanadium. The following results were obtained: No. 1, 0.585 per cent P; No. 2, 0.570 per cent P; No. 3, 0.625, per cent P; No. 4, 0.640 per cent P; No. 5, 0.572 per cent P; No. 6, 0.619 per cent P.

Ten grams of steel having 0.025 per cent phosphorus and 0.166 per cent vanadium. The following results were obtained: No. 1, 0.023 per cent P; No. 2, 0.018 per cent P; No. 3, 0.025 per cent P.

One gram of cast iron having 0.532 per cent phosphorus and 0.956 per cent vanadium added. The following results were obtained: No. 1, 0.539 per cent P; No. 2, 0.526 per cent P.

Pittsburgh, Pa.

Notes on Metallurgy in British Columbia in 1912.

By E. Jacobs.

The quantity of ore and concentrate smelted at the Consolidated Company's works at Trail was between 300,000 and 320,000 tons, which was less than in the fiscal year to June 30, 1910 (487,000 tons), and the next following fiscal year (389,000 tons). The decrease was caused by loss of the Snowshoe mine ore, of which there was 268,000 tons, received in the two fiscal years quoted. Improvements included an addition to flue chamber, to secure better results in settling of flue dust from copper ores; rebuilding of matte-handling plant, the method of treating low-grade matte having been changed; alterations to lead-sampling plant, made necessary by increase in quantity of coarse lead ore received; more electrolytic tanks in lead refinery, to provide for larger output of refined lead; and numerous changes, chiefly to facilitate handling materials. Experiments in reduction of zinc-lead ores were carried out, but no provision was made for production of spelter on a commercial scale.

Copper Smelting.

Last February, at the Trail smelter, experiments were commenced to smelt the raw matte pyritically, to take the place of the former more expensive method of roasting and sintering, and if possible without any considerable alteration to the furnaces already in use. The smallest furnace, dimensions 42 by 240 in., was blown in on a charge consisting of matte 2,500 lb., silicious ore 1,500 lb., lime rock 12 per cent, and coke 3 per cent. This furnace was blown out after having been in blast 12 hours, as it ran so fast the matte-tappers could not keep the matte down in the settlers. It was decided to cut the furnace in two, which was accordingly done, making the area at the tuyeres 42 by 120 in. The smaller furnace was then blown in on a similar charge, the coke being shoveled and the remainder of the charge dumped in from the side and distributed along the furnace by the locomotive in the same manner as for the ore-furnaces. The matte on the charge was coarse, about 6 in., while the silicious ore available was very fine, 50 per cent passing through a $\frac{1}{4}$ -in. screen.

The furnace was run on this charge for two days but never got properly heated, owing to the looseness and shallow depth of the charge. The next run was tried with a heavier charge and with matte crushed to 2 in., and, while this acted better, the sides of the furnace rapidly crusted, owing to the fine nature of the silicious ore. After several attempts with long-nosed cars and distributing plates, to try to get the charge into the center of the furnace, the ends were taken out of the hood and the furnace fed along the center with bottom-dump cars. This method proved successful. Two charge cars are used, and the charge of 4,200 lb. matte, 2,000 lb. silicious ore, 13.5 per cent lime rock, and 4 per cent coke is divided equally between the two.

The coke is fed by shoveling and the remainder of the charge is weighed in the cars—matte first, then ore, and lime rock on top. If the furnace shows signs of crusting the matte is weighed on top of the ore for a time, thereby throwing more matte along the sides, which invariably has the desired effect of cutting out the crust.

The matte is concentrated twice in this furnace, the first concentration running from 15 to 20 per cent copper, equivalent to a reduction of from 2.5 to 3 into 1. This matte is returned to the furnace and smelted with sufficient low-grade matte to keep the grade about 40 per cent copper for the second concentration. All the matte is tapped into Kilker's $\frac{1}{2}$ -ton matte-tapping cars (five of which are used), cooled, and hauled by electric trolley locomotive to the crushing plant.

The pans of the matte-cars dump directly into a 10 by 20-in. jaw-crusher and thence to a pan conveyor which discharges into three iron bins, whence the matte is drawn into V-shaped cars and hauled to the charge bins or shipped to Tacoma, Washington (for converting), according to grade.

Slag from the ore-furnaces assays, approximately: FeO, 14.5 to 16; SiO₂, 40 to 47; CaO, 18 to 22; MgO, 1.5 to 3; Al₂O₃, 14 to 16.5 per cent; S, trace. Slag from the pyritic furnace runs about FeO, 45 to 50; SiO₂, 35; CaO, 12 per cent.

This information was kindly supplied to the writer by James Buchanan, superintendent of the Consolidated Mining and Smelting Company of Canada's smelter at Trail.

The chief change at the Granby Company's smelter was in the substitution of water-granulation of slag for dumping it molten. By a system of conveying belts, operated by electric motors (already described in this journal), the dewatered slag is conveyed up a long incline to a height of 120 ft. and then dumped, this arrangement providing dump room for all slag that will be made for six or seven years. The quantity of ore from Granby mines treated in 1912 was more than 1,200,000 tons. One notable feature of the year's work was that the full battery of eight blast furnaces was operated all the year, one run having been for 156 consecutive days without interruption. The company is purchasing materials and plant, and other equipment for a 2,000-ton smelter, hydroelectric power station, shipping dock, etc., at Granby Bay, Observatory Inlet, where its new mine is being developed with promise of large productiveness.

The British Columbia Copper Company operated its smelter throughout the year. Ore receipts totalled between 650,000 and 700,000 tons. High efficiency was secured, monthly totals of ore smelted having ranged as high as 65,000 tons, with three furnaces in blast. The greater part of the ore smelted came from the Mother Lode and Rawhide mines. There is in the company's Lone Star mine a large amount of ore available, but owing to its high silica content, it has been deemed inadvisable to endeavor to smelt it with that from the company's other mines. For some time past concentration tests have been made with the object of determining how best to eliminate the excess of silica. The ore presents unusual obstacles to concentration, but notwithstanding this the problem is now in a fair way toward being successfully solved. Favorable results will have an important bearing upon the question of ore supply for the company's smelter. In value the general tenor of the ore is higher than that of the average of Boundary district ores.

Most of the copper concentrate and the ore shipped crude from Coast district mines was treated at the smelting works at Tacoma, Wash. This includes the comparatively large output of the Britannia mine.

Gold Milling.

While a large proportion, nearly three-fourths, of the lode gold produced in the province is obtained by smelting ores containing copper, the remaining one-fourth is recovered by stamp-milling and auxiliary cyaniding. The largest stamp-mill operated is that of the Hedley Gold Mining Company, at Hedley, Similkameen, where approximately 70,000 tons of ore was crushed in 1912, as compared with 58,000 tons in 1911. No gold is saved on plates, but fully five-sixths is contained

in concentrates from vanners and tables, while the remainder is recovered in cyanide bullion. Approximate value of gold recovered in 1912 was \$763,000, or an average of rather less than \$11 a ton; in 1911 it was \$680,000, with an average recovery of \$11.75 a ton. Estimated net earnings for 1912 were \$407,500, as against \$308,800 in 1911.

There were three 20-stamp mills operated in Nelson mining division in 1912, but information is not available concerning two. The third is that of the Mother Lode Sheep Creek Mining Company. During four months, July-October, 7,755 tons of ore was crushed. The extraction was nearly 98 per cent; the value of the product was \$102,869—average \$13.265 a ton. Operating expenses were \$7,245 a ton. November and December figures were not received. The mill is modern in its equipment. Higher net returns are expected from next year's operations.

A new installation was that of a 10-stamp mill at the Inland Empire mine, near Paulson, in the western part of Trail Creek mining division. Only a light saving is made on the plates. The daily output of concentrate is 30 to 40 tons, which is shipped to Trail for smelting.

Lead and Zinc Concentration.

The Standard Silver-Lead Mining Company shipped 4,400 tons of sorted ore to the smelter, and concentrated 32,600 tons of mill ore. Products were 5,400 tons of silver-lead and 3,300 tons of silver-zinc concentrates. Metal contents of all shipments were: Silver, 832,000 oz.; lead, 12,440,000 lb.; zinc, 2,706,000 lb. Silver-lead concentrate was shipped to Trail, B. C., and silver-zinc to Bartlesville, Okla. The mill has been run only one-shift per diem, but it is to be operated double shift hereafter.

The Van-Roi Mining Company, also operating near Silverton, Slocan Lake, concentrated 54,000 tons of ore. Average assay of feed showed: Silver, 15.02 oz. per ton; lead, 3.66 per cent, and zinc, 6.26 per cent. Concentrates produced, and metal contents were as follows:

	Metal Contents.		
	Silver, oz.	Lead, per cent.	Zinc, per cent.
Lead concentrate, 2,392.5 tons.....	179.75	60.2	11.1
Zinc concentrate, 2,570.5 tons.....	60.8	3.7	45.1
Tailing	4.6	0.9	4.0

An auxiliary aerial two-bucket tramway was constructed from mine to mill.

At the New Canadian Metal Company's mill, at Riondel, Kootenay Lake, operated in conjunction with the company's Bluebell mine, milling was resumed on July 4, after a long suspension of operations. During six months 33,000 tons of ore was milled; production was 49,600 oz. of silver and 4,172,000 lb. of lead. Capacity of mill is being increased from 225 tons to 300 tons per diem.

Several other concentrating mills were operated, but on a smaller scale than those above-mentioned.

General.

Gold and gold-copper ores are either milled or smelted in the province, with the exception of the latter ores in the Coast district, much of which is shipped to the smelter at Tacoma, Washington. Silver-lead and lead ores are either shipped crude to Trail, or concentrated and the product sent there, the Consolidated Company's lead-smelting and refining works being the only one reducing lead ores in British Columbia. Zinc-lead ores are concentrated and the zinc product, as well as crude zinc ore, is shipped to the United States, chiefly to Bartlesville, Okla., for reduction. The works of Beer, Sondheimer & Co., at that place, receive the zinc concentrate output of the Standard, Van Roi, Hewitt-Lorna Doone, and Monarch mines. The Lucky Jim and Noble Five mines ship "crude zinc" ore, the latter in much less quantity at present than the former. Noble Five zinc ore contains up to 56 per cent

B. C. Of this total, about 70,000 oz. came from British Columbia mines, 2,500 oz. from Yukon Territory (Canada), and 7,500 oz. from Alaska. Much of this gold was from placer mines.

The greater part of the 250,000 to 260,000 oz. of lode—also copper-bearing.

Regarding the bounty paid by the Federal Government on lead mined and smelted in the province, when the London price of lead is £14 or under, the amount of bounty payable is at the rate of 75 cents per 100 lb., but by the sliding scale the amount payable diminishes as the price rises, until, at £18 per ton it is entirely extinguished. During 1912 the lead content of ore and concentrate delivered to the smelter at Trail totalled, approximately, 22,000 tons. Bounty was payable until June, in which month the price rose to £18 and higher, and it remained higher than £18 throughout the remaining months of the year. Consequently the total amount of bounty earned in 1912 was only about \$65,000. The original appropriation made in 1903 was \$2,500,000; of this sum there remains unearned about \$700,000. The bounty payable under the present act "shall cease and determine on June 30, 1913," but those chiefly concerned are petitioning the Federal Government to continue to aid the local lead-mining industry in a similar or some other suitable form.

It may be of interest to note that the Dominion Director of Mines has had one of the officials of the Mines Branch of the Canadian Department of Mines engaged in an investigation of the Canadian market for various mineral products in a crude or partly prepared condition. The official referred to spent part of 1912 in British Columbia, and afterward continued his investigations in other parts of Canada. The ultimate object of this investigation is the further encouragement of the use of Canadian minerals as material in Canadian manufactures. It also includes pointing out to producers the requirements of the domestic market, and indicating the form in which minerals should be prepared for use in the various industries in which they are to be employed. The results of this work will thus set forth what minerals are at present in use in the manufacturing industries of Canada, their sources, the uses to which they are put, the degree of purity required for the various processes in which they are used, and the physical condition in which they are purchased.

In conclusion, it may be added that a preliminary estimate of the mineral production of British Columbia in 1912 indicates that it has been, in both quantity and value of mineral produced, a record year for the province. The estimated total value of the mineral production is \$31,500,000, of which nearly \$17,000,000 is for metallic minerals, and of this less than half a million is for placer-gold. The highest previous annual production was that for 1910—\$26,377,000. Estimates for 1912 show the following quantities of lode metals recovered: Gold, 250,000 oz.; silver, 2,700,000 oz.; lead, 35,000,000 lb.; copper, 50,000,000 lb.; zinc, 6,000,000 lb. The gross output of coal was 3,040,000 long tons, part of which was made into 263,000 tons of coke. Miscellaneous non-metallic minerals, other than coal, are estimated at \$3,800,000. The outlook is favorable for further increase.

The Efficiency Society will hold its annual meeting at the headquarters of the Society, 29 West 30th Street, New York City, on Monday and Tuesday, January 27 and 28. There will be symposia and discussions on management; on democracy in industry and securing the consent of the governed; on efficiency in the government organization, national, state and municipal or a readjustment of the governmental departments; on industrial relations; on the relations between employer, employee and the community; on industrial hygiene and safeguards against occupational disease and accident, and on safety. Mr. James G. Cannon, president of the Fourth National Bank, is the first president of the society. Among the other directors are Messrs. Bion J. Arnold, W. W. Freeman, William Jay Schieffelin and Schuyler S. Wheeler.

Approximately 60,000 oz. of gold was received in 1912 for assaying at the Dominion of Canada assay office, Vancouver,

Protection of Intellectual Property in Relation to Chemical Industry.*

By Dr. Leo H. Baekeland.

Intellectual Property Rights.

The mass of unthinking people, as well as those whose views are predominantly guided by precedent, have little or no conception of the natural rights of intellectual property. It is difficult to teach such people that adequate protection of intellectual property is abundantly more beneficial to the community at large than to the temporary individual possessors of these rights.

Yet these same people consider as sacred and inviolable, any other property rights as soon as the latter relate to chattels or real estate, whether such rights were obtained by purchase, by inheritance, by gift, by privilege, by labor, or by any other way.

Furthermore, the laws of all nations are very strict in protecting such property rights, but do not concern themselves, beyond certain limits, whether the possessor of the property is morally entitled to it or not. Neither do our laws concern themselves whether the owner uses his property for good or for wrong, for the benefit of the community at large, or for the gratification of his own selfish purposes. From the standpoint of the law (with very few exceptions, such as for instance, Board of Health or police ordinances, or cases of so-called eminent domain), it matters little whether the private ownership of some property is a burden to the community or whether it is an impediment to the happiness or the free development of its citizens.

Neither is there any dispute as to the time the ownership of such property should last. Except for restrictions put on ownership by taxes, property rights are practically perpetual, and can only be transferred by accepted methods, as for instance, sale, barter, inheritance, or donation.

In some rare instances, there may be expropriation for public purposes (or eminent domain), but even then, some suitable compensation is usually made.

All this is readily accepted as an axiom, as an underlying article of faith by all laws relating to property. Only the socialist dares dispute these rights, while even the single taxer admits them to such a decided extent that he desires to abolish taxes on all property created by labor or enterprise, so as to shift the burden of all taxation on unearned land values.

When, however, it comes to recognize the claims of ownership to intellectual property, the result of the truly creative effort of the citizen, we butt right away against some stubborn conceptions, which have petrified into the code of our long established laws.

If Tom steals Dick's two-dollar scarf pin, Dick will have little trouble in putting Tom in jail, even if Dick himself has obtained his pin by questionable methods. But when it comes to protect even for the short period of seventeen years, the most logical, the most legitimate personal property, intellectual property as embodied in patent rights, with all that it involves, with enterprises depending thereon, based often on the work of a life-time, then our law courts are woefully deficient, on account of the uncertainties, delays and enormous expenses connected with the adjudication of patent rights. All this works overwhelmingly in favor of the litigant with the well filled purse, the large corporation.

Fundamental American Patent Law.

Yet, no country in the world has expressed in a fairer and broader spirit, the rights of intellectual property, than the United States, in Article I, Section 8, of the Constitution: "Congress shall have power to promote the progress of science and the useful arts by securing for limited times to authors and inventors, the exclusive right to their respective writings and discoveries."

This proclamation lifted the right of a patentee at once far beyond the mere privilege conferred by most other countries, which grant patents not only to the real inventors or originators, but also to those who are first to introduce unpublished inventions into their respective countries. With some legitimate pride, we can say that in this respect at least, American patent law stands head and shoulders above the laws of Germany, France and England.

The principles of the right of intellectual property so clearly defined in our Constitution, were repeated in the preamble of the French Law of Jan. 8, 1791, which declares:

"The National Assembly, considering that every new idea, whose manifestation or development may become useful to society, belongs to him who conceived it, and that not to regard an industrial invention as the property of its author would be to attack the essential rights of man; considering at the same time how much the lack of a positive and authentic declaration of this truth may have contributed till now to discourage French industry by occasioning the emigration of numerous distinguished artists and by causing to pass out of the country a great number of new inventions from which the Empire ought to have drawn the first advantages; considering finally that all the principles of justice, of public order, and of national interest imperatively command that it determine for the future the opinion of French citizens with regard to this class of property by a law which consecrates and protects it . . . etc."

The wisdom of these provisions has abundantly been proved by subsequent events. Only a man stubbornly blind to evident facts, will deny that just those countries which have the most liberal laws for patent protection, are also those which have taken the lead in the industrial and scientific development of the world. No man was more imbued of the benefits of the patent system than Abraham Lincoln, when in 1860, in his speech at Springfield, Ill., he said:

"In the world's history, certain inventions and discoveries occurred of peculiar value, on account of their great efficiency in facilitating all other inventions and discoveries. Of these were the art of writing and of printing, the discovery of America, and the introduction of patent laws. . . . The patent system . . . added the fuel of interest to the fire of genius, in the discovery and production of new and useful things."

Inadequacy of American Patent System.

Up to about thirty years ago, our patent system covered tolerably well the purpose for which it was intended. It stimulated individual inventions and promoted numerous private enterprises. Since then, with the extraordinary growth of our nation, with the tremendous increase of agglomerations of capital for industrial enterprises, and more specially with the astonishing increase in the ramifications of applied science, our patent system has become totally inadequate to the needs of the country: it suits our new conditions in about the same way as baby clothes fit an overgrown boy.

Our patent system, although based on an excellent fundamental law, has now degenerated into a set of exceedingly complicated technicalities of law practice, a system of legal acrobatics, whereby any contestation before the courts can be turned into "perpetual motion" to the advantage of wealthy litigants, and whereby the individual patentees of slender means and the small industrial concerns, find themselves under smothering disadvantages when opposing rich antagonists. In this way, our patent system, instead of accomplishing its intended purposes of stimulating individuality, simply reinforces the rich and big industrial enterprises, and discourages the individual inventor unprovided with a liberal bank account.

New Rules of Supreme Court.

It is true that on November 4, 1912, the Supreme Court of the United States, has promulgated revised Rules of Practice for the Courts of Equity, which intend to simplify our methods of litigation. Unfortunately, this is only a half-way measure, leaving still abundant opportunity for the tactics of delay.

* Presidential address delivered before the American Institute of Chemical Engineers at the Detroit meeting, December, 1912.

chicane, and expense which have too much disgraced American patent litigation.

These new rules might gain in efficiency, if they were supplemented by the creation of a final court of patent appeals. They might be made incomparably more efficient if they could be strengthened by a system whereby the adjudication of the validity of patents does no longer devolve upon judges who do not possess the technical or scientific preparation required nowadays for discerning the merits of complicated patent questions. Some of the far-reaching details of scientific technology absolutely baffle the comprehension of those who have no preliminary technical or scientific training. Certain problems of chemistry and physics involved in many patent suits, can no longer be understood by an intelligent judge, if he has not had long and systematic preliminary training in that branch of knowledge. I do not deny that an intelligent judge can be coached and instructed by long, tedious, time-robbing methods, even in intricate scientific problems; but his education has to be made over again for each special case. After you have made a chemist of him for one case, the next adjudication will require the knowledge of a physicist, an electrician, an engineer, and so forth.

What would any judge say of a chemist or a mathematician, or an engineer, totally ignorant of the practice of law, who tried to conduct a law case in court? Such an amateur lawyer might succeed in doing so, but to what hopeless loss of time, misunderstandings, and confusions would this lead before the subject had been mastered to some extent. Yet this is exactly what happens with a judge to whom we entrust to decide on the validity of a patent involving highly intricate scientific or technical subjects.

Judge Hand expressed himself very eloquently on this subject:

"I cannot stop without calling attention to the extraordinary condition of the law which makes it possible for a man without any knowledge of even the rudiments of chemistry to pass upon such questions as these. The inordinate expense of time is the least of the resulting evils, for only a trained chemist is really capable of passing upon such facts, *e.g.*, in this case the chemical character of Von Furth's so-called "zinc compound," or the presence of inactive organic substances. In Germany, where the national spirit eagerly seeks for all the assistance it can get from the whole range of human knowledge, they do quite differently. The court summons technical judges to whom technical questions are submitted and who can intelligently pass upon the issues without blindly groping among testimony upon matters wholly out of their ken. How long we shall continue to blunder along without the aid of unpartisan and authoritative scientific assistance in the administration of justice, no one knows; but all fair persons not conventionalized by provincial legal habits of mind ought, I should think, to unite to effect some such advance."

(See *Parke-Davis & Company vs. H. K. Mulford Company*, Circuit Court, Southern District of New York, April 28, 1911—189 Federal Reporter, 95.)

Even under the new rules, it will not be difficult to drag on a case by presenting an unrestricted amount of testimony taken before an incompetent examiner, and by calculating every step so as to tire out your opponent, and so as to induce the judge in doubt and error, by swamping him with endless contradictory expert testimony calculated to befog the issue instead of making it clear. Such tactics are relatively easy for the litigant who, for that purpose, can afford to pay accommodating experts and skilful lawyers. Even if at the end, the judge, after laborious and conscientious efforts, masters the technicalities of the case and reaches a good decision, much needless time has been wasted. All this might easily be avoided, and judges might be saved the trouble and responsibility of going in every single case through a different scientific or technical training, if their intervention could be limited to what they are more competent for, namely, to determine what claims of patents have been infringed and in how far this infringement entitles the patentee to damages.

German Practice of Settling Patent Suits.

That such a method of settling patent suits is quite practical, is shown by the example of Germany. In that country, patents are allowed after preliminary examination, just like here; but, after the patent is granted, it can be attacked for annulment or revocation before a competent court in the patent office. So that any party who is sued for infringement of a patent which he thinks is invalid, can avoid temporarily the adjudication of the infringement issue by starting an annulment or revocation suit. In the meantime, the courts in which infringement cases are examined have to take the patent as it stands, and it is only left to them to interpret the scope of the claims, and to what extent these claims have been infringed.

This relieves the equity court of all the complicated questions of validity or non-validity of a patent, and puts this whole matter in the hands of a properly constituted court of experts who can handle this subject with incomparably less hesitation, or delay.

Besides this, the whole system of practice in the German Patent Office, tends toward systematic elimination of invalid patents. After an examiner has decided upon preliminary allowance of a patent, the claims and specifications are open for public inspection, and for a period of two months, anybody who-soever can file arguments against the final grant of the patent. In this way, the nation does not confer too lightly patent privileges and has furthermore, the benefit of the free advice of any experts in the art, who may advance good reasons for non-allowance of the claims, of which the examiner was not aware, when he rendered his first decision.

These opposition proceedings give added thoroughness to the work of the examiners. They are relatively inexpensive and do not necessitate the intervention of law counsel. Sometimes they delay the issue of a patent, if there is any good reason for doing so. On the other hand, a patent that has successfully withstood vigorous opposition proceedings is very much strengthened thereby; this, in itself, is a very valuable compensation for any delays to which the patentee may have been subjected. In other words, by that system, a good patent becomes stronger, while a defective patent application is easily weeded out. A similar system of public opposition exists here in the United States in relation to the granting of trademark rights, and seems practical enough that it could be extended to our methods of allowing patents.

Such a sifting process, first by the examiner, then by opposition proceedings, sometimes by annulment or revocation proceedings, for wrongly issued patents, involves no serious difficulties nor great loss of time if carried out by courts of experts. Thanks to such a system, the work of a judge who acts on an infringement case, gains considerably in dignity and is, at the same time, enormously shortened and simplified. (See *Wertheimer, The German Patent System*, Electrical World, May 18, 1912.)

Proposed Changes of American Patent Office.

The German system throws the burden of technicalities and expert knowledge on the patent office, or the courts connected therewith. Nothing would be easier than to introduce a somewhat similar system in our country:

All officers of our patent office, high or low, should be made independent of any political favoritism; they should be better paid, with more opportunity for promotion, according to merit; their work should be made simpler by an improved office equipment and increased facilities for a thorough search; furthermore, our unnecessarily complicated and expensive methods of interference proceedings should be simplified.

With these reforms, there is no doubt that we can organize right in the patent office, a competent court, supplemented by the court of appeals of the District of Columbia, for deciding in a very expedient way, all questions of validity of patents.

This court of appeals, because it is situated right in Washington, would have easy and immediate access to all the records of the patent office; by this fact alone, it would have superior opportunities for prompt and efficient work.

During the late years, Germany has been trying to broaden its patent laws more and more toward the principles set forth in the American Constitution. For instance, it has practically eliminated the system of compulsory licenses except in some rare instances where public welfare is involved. If only we could borrow some of the more efficient methods with which the German patent law is administered and enforced, we might succeed in making an American patent *real* property for poor and rich alike, instead of a pretext for expensive and endless litigation with all the advantages it gives to the richer litigant, to the detriment of the consumer, who in the end, pays the bill.

Deficiencies of Proposed Oldfield Bill.

At least some of these facts seem to have been very well recognized in the masterly report of Hon. William A. Oldfield, chairman of the House Committee on Patents. (See report No. 1161, on H. R. 23,417, Aug. 8, 1912.)

Unfortunately, his proposed Oldfield Bill (H. R. No. 23,417) with a regrettable lack of consistency, neglects utterly the paramount issues, and busies itself with secondary regulations which if carried out will practically put a penalty on patented articles.

The new provisions of the Oldfield Bill aim at curtailing the power of patents in the hands of trusts or large corporations; but, in doing so, new provisions are introduced which will create endless new opportunities for protracted litigation.

The Oldfield Bill overlooks the axiom that whatever increases the expense or delays of litigation, is a very potent weapon in the hands of large corporations, which they can hurl against the poor litigant who stands in their way.

The saddest thing of all is that the new Oldfield Bill tries to abrogate the hitherto accepted principle established by our Constitution, that a patentee has the right to license or sell his patent on whatever terms he pleases. It has been feared that this principle, if carried too far, might become a dodge for avoiding anti-trust laws. Since the decision of the famous, but harmless, Dick case, the most hysterical exaggerations have been published on this subject. Fortunately, since then, the recent and unanimous decision of the United States Supreme Court in the "bath tub trust" case, Nov. 18, 1912, does away with all these redundant arguments and settles, beyond doubt, the principle that, patent or no patent, unlawful combinations in restraint of trade, can be stopped by the Sherman Law.

A Penalty on Patented Articles.

The Oldfield Bill, in its eagerness to avoid any hesitation on this subject, goes one step further, and unfortunately one step too far. It puts so many restrictions on the sale of a patent article, or on a patent license, that it may become a positive disadvantage to transact business by means of patents.

Examined in last analysis, it threatens a business based on patented processes or patented articles, with penalties which unpatented articles thus far are not subjected to. It takes the proposed patent law as a pretext for saddling a patented article with restrictions which have not heretofore been formulated for non-patented goods.

This unexpected paradox, promoted by the Oldfield Bill, is distinctly in opposition of the rights of intellectual property conveyed by the words and the spirit of the Constitution, and if the Oldfield Bill becomes an effective law, it will be the saddest blow ever given to our patent system. It will do comparatively little harm to large business interests, because for them, there are many ways of circumventing its provisions; on the other hand, it will cause great discouragement to smaller enterprises who, until now, have held the hope of matching inventive genius and initiative against the money power of big organizations. Make a large corporation respect the patents of a small concern, or of an individual, and you reduce at once any advantage of size or money power, and at the same time, you encourage the most beneficial form of competition, competition based on improvements. But to introduce curtailing restrictions for the licensing or selling of patented articles or patented processes to which non-patented articles are not subjected to, means simply obliterating the value of patents while needlessly

increasing still further the opportunities of endless and ruinous litigation and chicanery.

Suppression or Non-Use of Patents.

Another unfortunate miscarriage of purpose in the Oldfield Bill is its provision against so-called wilful "suppression" or "non use" of patents. It does not take into consideration that in numerous instances, a patentee or an assignee possesses a series of so-called alternative patents, which can be used to bring about identical or similar technical results by modified means. Among such alternate patents, the best or the most suitable is used, absolutely irrespective of any other reason or intention to suppress their use. Yet without the exclusive possession of every one of these patents, the invention would not sufficiently protect against competitors, and the field would be so much reduced as not to make it worth while to put one's best energies to the development of the invention.

In most cases, it would become a material impossibility for a small concern to maintain the exclusive ownership of its patents, if it had to go to the enormous expense of working simultaneously all its "alternate" patents; by omitting this expensive technicality, it would be exposed to the risk of being compelled by its competitors to grant a compulsory license; this would practically annihilate the advantage of exclusive ownership as expressed by the Constitution.

There again large concerns would be at an overwhelming advantage because they can at an expense relatively small for them, equip the necessary appliances for remaining within the technical provisions of the law. In the meantime, they could easily harass their financially weaker competitors in exacting from them compulsory licenses which would break up the only prospects of successful competition which the smaller concern might have possessed, until then, in its patents.

In other words, the Oldfield Bill is aiming at the petty side of the situation, and in doing so, has unwittingly picked out a vital spot of our patent system. It reminds one of the man who set his barn afire in order to drive out a hornet's nest.

I have no doubt that this bill has been framed with the best intentions for the interests of the country. Unfortunately, the framers of this bill do not foresee the far-reaching and dangerous effects of its provisions.

One-Side Popular Conception of Inventions.

The average man, even the average legislator, has a rather one-sided conception of patents or inventions. Most people's idea of a patent does not go far beyond some simple mechanical device, like a patented mole-trap, a safety razor, an alarm clock, or other similar invention, more or less easy to understand after the apparently simple mechanical principles have once been explained. Then everything seems so simple and easy to them, that their limited imagination cannot conceive how even these apparently simple devices have frequently cost incredible efforts and immense amounts of money before their advantages became available to the public.

This attitude of mind develops, naturally, the belief that a patentee has a "soft snap," the result of a lucky idea, in about the same way as a lucky prospector strikes a rich gold mine, or a lucky ticket draws the grand prize in a lottery.

Precisely on this account it becomes difficult to explain to such people the rights and purposes of intellectual property; it is still more difficult to convince them that the nation is greatly benefited by liberal patent laws.

When it comes to chemical patents, the ignorance of the average public is amusing if not pathetic. Since we have heard a New York alderman in an official address of welcome to members of the International Congress of Chemistry speak as if they were druggists or pharmacists, we must no longer be astonished if the average Congressman or Senator refers to a chemical patent as a synonym to "patent medicine."

The Far-Reaching Effect of Chemical Inventions.

But even to the better prepared legislators, it is difficult to understand how some chemical inventions have brought about the most far-reaching developments, not only in other industries and arts, but on civilization itself.

For instance, it is not so obvious to them how processes for fixing the nitrogen of the air or extracting soluble potassium salts from rocks, enable us to make food supplies independent from the restricted potash mines in Germany or the nitrate deposits in Chili. Such inventions are no more nor less than means for preventing possible starvation of our race.

Do they realize that the development of the automobile, with all what it directly and indirectly implies, was entirely dependent on Goodyear's vulcanizing process of rubber?

Shall we remind them of the fact that without the invention of explosives, like dynamite, gigantic engineering enterprises, the Panama Canal, blasting of rock for the excavation of our cities, mining for ores, tunneling and grading of railroads, would be impossible?

How could we expect even the most perfected modern printing presses to distribute to every citizen, rich or poor, young or old, that knowledge and culture, which means better citizenship, better opportunities for happiness and development of our race, if it were not for the inexpensive and abundant supply of paper furnished by the cellulose processes. The Greeks, the Romans, and even the Middle Ages had their sages, their poets: yet those were the times of slavery and oppression, because knowledge was only in the reach of such a limited number that it was possible for tyrants to throttle its diffusion by sending the few advanced thinkers to the gallows or burning them alive. For the same reason, scarcity of books, the destruction of the library of Alexandria, was a calamity for the intellectual development of mankind. Our abundant supply of cellulose makes a repetition of such conditions an utter impossibility.

Then, again, where would we find our supplies of steel, the main raw material for modern engineering, if the Bessemer, the Thomas-Gilchrist and others had not invented their processes? How about the marvelous synthesis of products derived from coal tar, which have literally created the most astounding series of new substances which have revolutionized therapeutics, surgery, hygiene, and are finding daily new applications in the most varied arts and in general technology?

The Increased Cost of Living in Its Relation to Invention and Patents.

At a time when all countries are confronted with that critical question of the increased cost of living, it may be interesting to point out that just those industries where invention and patents have played the smallest rôle are also those where the increase of price is most burdensome, while those commodities where patented inventions have had the fullest influence have, on the contrary, decreased in price, and in some instances, to an astonishing degree.

For instance, the price of sulphuric acid is about fifteen times less than it was in 1807 and about one-half of that of 1870. The price of soda ash is about one-sixth of what it was in 1823, and about one-half of the price in 1860. Nitric acid sells for less than one-half the price of 1861. Glycerine sells for about one-eighth of the price in 1855. Chloride of lime in 1800 sold for 30 cents a pound, in 1870 for about 2 cents per pound, to-day for about 1 cent a pound.

Any chemist knows that every one of these products is used directly and indirectly in the most ramified channels of our arts and industries, but the layman does not know that cheap soda means cheap soap, cheap paper, cheap glass, etc.; that cheap sulphuric acid means cheap fertilizers, better crops, cheaper corn, cheaper wheat, and so forth.

Let me point out that the decrease in price of these materials, even considerably greater than the bare comparison of figures indicates, if we take in consideration that the purchasing value of money has considerably decreased, while the cost of labor has enormously increased.

Nor are these examples nearly confined to chemical products. The reduction in price for articles where patents have played an important rôle is just as evident in steel products, tools, machinery, etc.

Compare these lower prices with the vastly increased cost of

rents, clothing, foodstuffs, and many agricultural products, where patents have played a less preponderant rôle. If you will carry your analysis still further you will find that in such branches of trade where patented inventions have had little or no importance, for instance, cattle raising, prices have soared highest. On the other hand, for such agricultural products where patented machinery could be used to best advantage, like wheat and corn, the increase of price has been relatively small. Then, again, garden vegetables, potatoes, etc., where the use of patented agricultural machinery is less available, show an enormous increase in price.

You may object that the price of shoes has gone up, but here again, the increase is entirely due to the greatly advanced price of hides, and were it not for the perfected shoe-making machinery, and for the better and cheaper chemical tanning methods, all due to patents, the cost of our shoes would be so high that they might again become an article of luxury, available only for the well-to-do.

The present price of clothing is high enough as it is; nevertheless, it would still be much higher but for the patented machinery for spinning and weaving, the patented chemical processes of bleaching, dyeing, mercerizing, etc.

I should not omit to mention our vastly improved and cheapened methods of transportation, of production of power and light, all developed and perfected on an interwoven system of patents: I could explain the far-reaching influence thereof on civilization, culture, on the happiness and security of life of the individual citizens; but even then I might not convince the pessimist or the scoffer who only sees the hole in a doughnut and stubbornly persists in ignoring the doughnut itself.

The Genesis of an Invention and the Incentive of a Patent Property.

The history of almost every invention which we are utilizing now, unconsciously, every day, is an epos by itself, the details of which are only known by the few pioneers who gave the best they had to give, who helped with their brains, with their money, and talent of organization; some with their very lives.

The oft repeated statement has been made: "An inventor cannot help inventing, whether you give him a reward or not." Then again, some others say: "Necessity is the mother of invention."

The most apparent fact is that the man who receives an ample income from his father, or some other privileged source, is less prompted to distinguish himself by arduous creative work on inventions than the poor but intelligent man who sees in invention a means of making himself financially free and independent, as well as giving an outlet to his inventive abilities.

Whoever has followed intimately the development of some chemical processes knows very well that whether "the inventor cannot help inventing," or whatever may be the incentive to invention, most of these important inventions could never have been carried out, or could never have been brought to the point where they became of public benefit but for the intelligent use of vast sums of money.

Too few people have a conception of the immense sacrifices, of the serious money risks, involved in the development of some patents. Many chemical inventions used now currently and open to the public at large have cost millions before they were brought into practical shape or before the public was educated to their advantages. Can any one expect that such expenses, such efforts, such risks would be undertaken unless there was the possibility of at least some chance of recouping by a temporary patent protection?

The Large German Chemical Corporations.

Let us take, for instance, those large German chemical companies, which employ hundreds of chemists and engineers, engaged exclusively in research work; to them we owe the development of many processes which have had an untold beneficial influence in many directions of the economies of our daily life, even on civilization itself.

They employ large aggregations of capital, reaching into many millions. The dividends of some of these companies may appear large to the superficial observer. Yet if you look more closely into it you will find that these very companies were founded long ago, some of them over half a century or more, that the large capital which they employ has never been "watered," that, although they have had the benefit of the devoted co-operation of an endless number of distinguished men, stars of first magnitude in their profession, the net returns on their invested capital, at the end of half a century of brilliant intellectual pioneer work, is relatively small, even if the dividends seem large. In fact, the net returns are decidedly lower than that of many American enterprises not over fifteen years old, and where progressive technical leadership was entirely lacking, but where tariff privileges and agglomeration of competing concerns into a trust insured a splendidly paying monopoly, notwithstanding the reckless financiering of their promoters.

If you will further investigate the history of those German chemical concerns which have become leaders of the industrial world by nothing but their intellectual pioneership, you will find that notwithstanding all the patents on which they have to rely the expenses involved in research work and pioneership, swallow up, to a large extent, the profits realized in some of the established branches. But with true scientific spirit their farsighted directors were willing to sacrifice a very considerable part of their earnings in their search for improvements and development of new ideas; they have set a magnificent example in the only competition beneficial to the public—*competition by improvement*.

One of our wealthiest retired multi-millionaire manufacturers, not so long ago, speaking about his money successes, gave the following advice: "Never be a pioneer; it does not pay. Let the other man do the pioneering, and then after he has shown what can be done, do it bigger and more quickly; but let the other man take the time and the risk to show you how to do it." To any one who advances the statement that an inventor "cannot help inventing," I desire to ask whether an inventor will do much inventing, if in order to carry on his research work, or to develop his intention, he has to spend hundreds of thousands, nay, sometimes millions of dollars, but does not possess them, and nobody is willing to take the risk to furnish the money unless there is a fair chance for his backers of obtaining some compensation by a temporary patent protection? Those who know the large sums of money which have been swallowed up by the research and development work connected with the artificial production of nitrates, with the Solvay soda process, the development of the steam turbine, electric light, electric traction, and numerous other inventions of far-reaching magnitude, will know what I mean.

Just on this account it is highly unreasonable of the Oldfield bill to try to make a distinction between the inventor in whose name the patent is drawn and the party who runs the risks in enabling the inventor to make the invention available to the public; any such legislation simply tends to discourage those who, at considerable risk, furnish the capital and the talent to develop an invention into a commercial possibility, and who thereby bring it into real public service.

The Gap between Invention and Commercial Success.

Now and then I have perceived that some of my fellow chemists, who, although highly trained, have never created anything of technical value and whose experience with matters of practical life frequently extends not beyond the confines of their lecture room or their laboratory, do not seem to grasp fully the immense distance that lies between the initial conception of an invention, or its study in the laboratory, and the overwhelming amount of careful work and money risks connected with its development on a commercial scale, until it has safely reached the point where the public can avail itself of the invention.

I wish to cite, for instance, the famous Solvay process, which gives us cheap, excellent and abundant soda, an article of

prominent importance in the wheels of our civilization. This process was known and described more than a dozen times, and had even been tried repeatedly at considerable loss on a commercial scale, many years before Solvay tied his genius to this difficult problem and developed from an unreliable laboratory reaction a process of great industrial importance, then, with a staff of able collaborators, and the employment of large amounts of cash, he overcame, by and by, the technical drawbacks which had caused the failure of all of his predecessors.

Hundreds of similar examples could be cited. Whoever has been intimately acquainted with the commercial development of some of the most successful inventions knows quite well the risks, dangers of failure, which have accompanied the herculean task of development and educational work. It is a well-established fact that the great majority of new enterprises fail, that few succeed.

The Educational Effect of Inventions.

The educational effect due to the introduction of patented inventions is of immense benefit to the public, although this fact is not very apparent to most people. In many instances the owner of a patent frequently has to go to extreme sacrifices before he succeeds in convincing the public of the merits of his invention; in fact, the public stubbornly refuses to benefit by an improvement to which it has not been fully educated.

The practical value of cash registers only became obvious after a most thorough and expensive educational campaign.

The metric system is just as useful as the cash register; it was invented long ago and systematized in all its details during the first French Republic. Nevertheless, to-day, there are still two large commercial countries, the United States and England, which have not yet been educated to its merits; if the metric system had been patented, like the "cash register," somebody, during the seventeen years of the patent monopoly, would have undertaken the money risk and arduous task of thoroughly explaining the advantages of the metric system to our conservative citizens, and we would have ceased long ago to submit to the burden of waste of time and money caused by our antiquated, cumbersome system of weights and measures.

It has been stated, with much reason, that the best way to postpone the benefits of an invention is to allow public use of a patent, because then nobody takes the risk of starting an educational campaign or of developing the invention, which, after all, means pulling the chestnuts out of the fire for the benefit of others.

Entirely new industrial enterprises are not easily started on inventions which are not patented, unless some other method is available for insuring some kind of a monopoly: for instance, by maintaining secrecy or by acquiring special skill, or by controlling the raw material, or by tying the market, or, in other instances, where the initial outlay for a plant requires a capital so large as to exclude others.

Moreover, if you scrutinize those industries where secrecy of methods, instead of published patents, is the prevailing tendency, you will find that the secret-process industries are precisely those which have least progress to record and where high prices rule.

Whoever desires to get posted on the modern literature pertaining to any industrial chemical processes will find that available text-books are many years behind in information as far as novelty and accuracy are concerned; for this reason alone, it is absolutely indispensable to get acquainted with all recent patent literature.

Were it not for the compensation expected from patent rights most of this information would be carefully kept secret, or, if it were divulged at all, this would mostly occur by accident. Every newly published patent sets to work the thinking cells of numerous inventors, who are not slow to suggest further possible improvements. Every patent of some importance is rapidly followed by a succession of other patents conceived by other inventors who were inspired by their predecessors and so the work of progress goes on unceasingly and at a quickened pace.

In the age of the alchemists there were no patents; inventions and discoveries were jealously guarded and buried with their originators, and the world and its inhabitants remained very much what they were, with most rights and comforts in the possession of those in power, and very little chance of improvement for the non-privileged classes.

What Can Be Done?

The public should be educated in these truisms. Unfortunately, the education of the public has been directed in the opposite way since patent infringers have utilized the daily press after the late decision of the Supreme Court in the Dick case to start a campaign for urging our well-meaning but ill-prepared legislators towards patent reform, which will give still broader scope to our modern buccaneers. This reminds of the man who, after stealing a stranger's pocketbook, kept on shouting "stop thief," so as to distract the attention from himself.

Two ways are open for our legislators:

One way is to try "to hit the trusts" by mutilating the best there is in our patent system, which has been such a potent factor in the development of our country; to chill the best incentive for private enterprise; to stunt that kind of competition most beneficial to the public, competition by improvement, incomparably better in this respect for stimulating industry, science and progress, than protective tariff privileges which, in many instances, have worked in the opposite direction.

The other way is not to put dangerous restrictions on the patent rights defined by our Constitution. If there has been any fear that such patent rights might be abused for evading the provisions of the anti-trust laws these apprehensions have vanished by the clear, unequivocal decision of the Supreme Court in the bath tub case.

But there is urgent need of reform in our patent system by simplifying procedure in the Patent Office as well as in the courts by insuring better, quicker, and less expensive means for adjudicating the title and validity of patents. Only such a reform will bring about that big or small, poor or rich alike may be stimulated by the advantages of our patent system, instead of making a patent an expensive but powerful instrument available only to the wealthy.

Whatever simplifies and lessens the cost of the administration of our otherwise excellent fundamental patent law gives the enterprising man with small means a better chance of competition by inventive progress and merit against ponderous aggregations of capital. By such reform, which insures such healthy competition, the nation is sure to be benefited.

In all above considerations my remarks were principally inspired from the standpoint of chemical patents, not alone because this very important class of patents is least understood by the average public and the legislator, but because chemical process patents are also those which are most difficult to protect them from infringers.

The University of Pittsburgh is undertaking an investigation of the smoke problem, and has issued *Bulletin No. 1*, containing an outline of the work.

The indexing of mining literature receives attention in the *Quarterly* of the Colorado School of Mines, Golden, Colo. Carl A. Allen, assistant professor of mining, has completed an extension of the Dewey Decimal System of Classification as applied to mining.

Semi-Automatic Furnaces.—The W. S. Rockwell Company, of 50 Church Street, New York, has issued illustrated catalog 16 on the Rockwell semi-automatic furnaces for annealing, hardening, tempering, heat treating and miscellaneous heating operation. This type of furnace has been developed to provide a means of uniformly heating large quantities of material of irregular shape and sizes and which cannot be well handled by an automatic furnace of the rotary or conveyor type nor is it economically heated by the ordinary stationary furnace. The "semi-automatic" furnace is of the stationary form, but the material to be heated is conveyed through it mechanically in a continuous or nearly continuous manner.

Measurement of Temperature by Electrical Means.*

By Chas. Burton Thwing, Ph.D.

The measurement of temperature, as compared with the measurement of other physical quantities, is beset with many difficulties, since temperature is a quantity which cannot be directly measured, as are length and weight, but must be inferred from the change in various physical properties, either of the body itself whose temperature is to be measured, or of other bodies in contact with it.

The changes, for example, in volume of the standard body, or thermometer, as it is called, for each temperature in its range, having been previously determined, the body and the thermometer are brought in contact and allowed to remain in contact until they have reached thermal equilibrium, when the temperature read from the thermometer is assumed to be the temperature of the body. It often happens, however, that both the body and the thermometer are immersed in a medium whose temperature, like the air of a gas furnace, is changing rapidly. In this case, if the body is large and the thermometer small, the thermometer will respond more quickly than the body and give false indications of the temperature of the body.

One of the earliest methods of comparing temperatures is still, for many purposes, one of the most accurate and convenient, i.e., the change in volume of a liquid, like mercury or alcohol, contained in a glass bulb, terminating in a slender tube. There are certain circumstances, however, under which the mercurial thermometer fails to meet all the requirements; first of all it is not suitable for measuring high temperatures; secondly, it is often inconvenient or impossible to so place the thermometer that it is in contact with the body whose temperature is to be measured, and at the same time accessible to be read; thirdly, it is not at all well adapted for making a graphic record.

The various types of electrical instruments for measuring temperature have proved very adaptable over a wide range of temperature, in the most inaccessible situations, and are admirably adapted to produce graphic records at any distance. The increasing use of such instruments, both in research work and the numerous lines of industrial operations, makes it desirable that engineers should be informed as to the general principles on which electrical temperature measurements are based, and that they should have some notions as to the availability of the different types of such instruments best suited to various conditions.

Leaving out of the question certain optical pyrometers, in which an electrically heated body is used for color comparison, there are three different types of electrical instruments used for measuring temperatures: (A) the simple thermocouple, connected to an indicating or recording galvanometer; (B) the radiation type, consisting of a device for collecting the rays at the junction of a sensitive thermocouple, which is connected to an indicating or recording galvanometer; (C) a resistance which varies with the temperature, used in conjunction with a suitable indicating or recording potentiometer or millivoltmeter, for measuring the variations in resistance, which may be either in the nature of a Wheatstone Bridge or a direct reading ohmmeter.

I shall proceed to describe the three types of instruments in the order named, and then discuss briefly the suitability of the various types for making measurements under some of the varying conditions which occur in practice.

Simple Thermocouple.

In the Type A instruments, the thermocouple is composed of two wires or rods of unlike metal, securely joined together, by twisting, riveting or welding, at one end, this junction being known as the "hot junction," and connected at the free ends to copper leads which convey the current to the millivoltmeter, the scale of which is ordinarily graduated in degrees of temperature, or, in other words, is "direct reading." This point of connection between the elements of the thermocouple and the cop-

*A discussion before the Philadelphia Section of the American Institute of Electrical Engineers.

per leads is commonly referred to as the "cold ends" of the thermocouple.

Only a limited number of metals is available for use as thermocouples, since the thermoelectric difference of potential is small for some of them. The choice narrows down in practice to copper, iron, nickel, and platinum, and the alloys of nickel and platinum. The first thermocouple to be employed was that known by the name of LeChatelier, consisting of platinum for the negative against platinum-10 per cent iridium for the positive element. The platinum-iridium alloy is at present almost wholly displaced by the use of platinum-10 per cent rhodium, which, although it gives a somewhat lower e.m.f., is more constant under continuous use for high temperatures.

The platinum thermocouple may be used for temperatures as high as 1600 deg. C. (3000 deg. Fahr.) for short intervals, but under long exposure, even when protected in the best porcelain tubes, the evaporation of the platinum at the "hot junction" and its absorption by the platinum-rhodium gradually reduces the e.m.f. of the thermocouple. Moreover, the failure of the porcelain tube to prevent the access of various contaminating gases to the platinum thermocouple permits in time such alterations in the couple as to necessitate frequent recalibration. The high cost of platinum makes it necessary to use very small wires, a circumstance which not only aggravates the faults above mentioned but introduces errors of considerable magnitude, due to the varying resistance of the thermocouple when immersed to varying depths in the heat.

These considerations led to the search for base metal thermocouples, some of which have proved to be, in many respects, superior to the platinum thermocouples for temperatures up to 1000 deg. C., at least. For the positive element of such thermocouples, which are to be used for temperatures as high as 1100 deg. C., an alloy of nickel with 6 to 10 per cent chromium is one of the most suitable. For the negative element, a nickel alloy with a small percentage of various other elements is used. This thermocouple has an e.m.f. about $3\frac{1}{2}$ times as great as the platinum thermocouple at 1100 deg. C. (2012 deg. Fahr.). These materials are, moreover, so much cheaper than platinum that the thermocouple can be made of larger size, thus eliminating very largely both the error due to the surface contamination of the elements and the error due to the varying resistance with varying depths of immersion. The latter error is still further reduced by the fact already mentioned that the e.m.f. of the couple is higher, thus permitting higher resistance in the galvanometer.

Where the maximum temperature does not exceed 900 deg. C. (1652 deg. F.), a nickel alloy consisting of about 41 per cent nickel with 59 per cent copper, used as the negative element against the above mentioned chrome-nickel alloy, or either copper or iron as the positive element, gives an exceedingly constant e.m.f. as well as a very high one; the e.m.f. being about six times that of platinum, at 900 deg. C., and exceedingly constant even after long use. This alloy, which is known as constantan, has the added advantage over platinum of having a very small co-efficient of resistance even for high temperatures, so that the error due to the varying depth of immersion of the thermocouple becomes practically negligible. The high e.m.f. of this couple makes it especially suitable for low temperature measurements; indeed, for all temperatures below 900 deg. C., it is preferable to platinum for thermocouples, even though here were not the difference in cost.

Limitations of Thermocouples.

The extreme simplicity of the thermocouple makes it one of the first means to be considered when electrical temperature measurements are to be made. It has, however, two faults; first, the quantity of energy available is small, so that the millivoltmeter employed must be much more sensitive than the electrical instruments employed for most commercial purposes. The e.m.f. of the platinum thermocouple is but 18 millivolts at 1600 deg. C. (2912 deg. F.) and that of the nickel thermocouples but 60 millivolts at their respective highest ranges. With the best modern designs of millivoltmeters there

is, however, no difficulty in making accurate instruments to measure the small amount of energy available, except where the range of temperature covered is small. Under these circumstances, it is sometimes best to use a number of thermocouples in series, though it is often preferable to adopt the resistance type of instrument, especially if the temperature is low.

The second objection is a more serious one, where measurements are required to be of extreme accuracy, and most serious when the range of temperature is small. This is known as the "cold-end error." It must be borne in mind that the e.m.f. which is measured by the galvanometer is a quantity which varies with the difference in temperature between the hot junction and the cold end of the thermocouple, or where the copper wires leading to the galvanometer are joined to the elements

FIG. 1.—E. M. F.—TEMPERATURE CURVES FOR THREE TYPICAL THERMOCOUPLES.

of the thermocouple. If the instrument is calibrated for a "cold end" temperature of, say, 25 deg. C. (80 deg. Fahr.), it will read too low if the cold ends are at 30 deg. C., and too high if the cold ends are at 20 deg. C. It is quite commonly possible, where high temperatures are to be measured, to place the cold end at a point near the floor, or underground, or in contact with steam or water pipes, so that it may be maintained at a temperature which will not vary far from a standard fixed temperature. Of course, it is possible, when special refinements of temperature measurement are required, to observe this cold end temperature and make the necessary correction for it. In

FIG. 2.—RADIATION PYROMETER.

research work, or for calibration, the cold ends are immersed in ice water.

The curves shown in Fig. 1 illustrate the temperature e.m.f. relation of the three typical thermocouples mentioned above.

Radiation Pyrometer with Thermocouple.

Type B is available for temperatures which are too high for platinum thermocouples, or for situations not easily accessible, even where the temperatures are not too high, as, for example, in a large furnace, or at the surface of materials in motion, such as masses of steel passing through rolls or under the hammer. In this instrument, use is made of the law connecting the total energy radiated by a body with its temperature. This law is known as the Stefan-Boltzmann Law, and is expressed in the equation $E = K(T^4 - T_c^4)$ where E is the total energy radiated by a body of absolute temperature T , and K is a constant depending on the units used. This law has been found to hold not only for the highest temperatures measurable with gas thermometers and thermocouples, but has been found to give

results in perfect harmony with measurements made by employing optical pyrometers, in accordance with the law of Wien, as high as 2600 deg. C. (4712 deg. Fahr.).

The method consists, as stated, in collecting all the radiations, both luminous and non-luminous, from a limited area of the body whose temperature is to be measured and concentrating them upon the blackened junction of a sensitive thermocouple. In the form employed by Féry, the rays are collected by means of a concave mirror, and are focused upon the junction of the thermocouple by means of an ingenious optical device, contained in an eye-piece attached to the telescope.

In the simpler form devised by the writer, the radiations are concentrated by means of a conical aluminum mirror. Since the radiations are transmitted down the conical mirror by means of multiple reflections, as shown by Fig. 2, the mirror is equivalent to a fixed focus mirror, for the rays entering the cone through the diaphragm are transmitted to the outlet, and strike the thermocouple, regardless of whether or not they are parallel on entering the cone. This makes the instrument exceedingly convenient to use in foundries and rolling mills, and other places where the quick motion of the men would be interrupted by the use of an instrument which required mounting in one position for any length of time. The quickness of action of this instrument is further increased by the extremely small dimensions of the thermocouple, the heat capacity of which is so small that equilibrium is reached in five seconds after pointing the receiving tube of the instrument at the hot body.

This instrument has found application, both in the indicating and recording forms, for use in steel and rolling mills, steam boilers, smelting furnaces, and in the large rotary form of kiln used in cement burning and the nodulizing of iron ore. The portable form is used for taking the temperature of molten steel, both before tapping from the open-hearth furnace, as well as after tapping, and while pouring, and for taking the temperature of tools made of high-speed steel, in hardening furnaces, where it is desirable to indicate not so much the temperature of the furnace as the temperature to which the work itself has been heated. This type of instrument is not only capable of a high degree of accuracy in measurement but, since it is not exposed to any high temperatures, it deteriorates much less with use than any other form of electrical pyrometer.

Electric Resistance Pyrometer.

Type C, or the Resistance form of electrical pyrometer, has been employed for all ranges of temperature from that of liquid air to temperatures as high as 1100 deg. C. (2012 deg. Fahr.). For this higher temperature, the problem of protecting the resistance coil from mechanical damage, as well as from the contamination of the platinum by the presence of any foreign gases, becomes a very serious one.

The slightest admixture of any foreign material with platinum alters its resistance very appreciably, so that it becomes necessary to protect the coil both with a porcelain tube and an additional covering of nickel. The nickel protection, of course, is only durable at such temperatures as are the nickel thermocouples, and the whole bulb is much more expensive to install and maintain than the thermocouple.

For temperatures below 200 deg. C. (392 deg. Fahr.), resistance wire of pure nickel is employed. This has the advantage of low first cost and constancy in its indications over these low ranges of temperature. The coil is enclosed in a tube of varying shape and material, suited to the conditions under which it is to be used, and is capable of taking measurements comparable in refinement with those made by the best mechanical thermometers. The same bulb may be employed for measuring all temperatures from the transformation point of nickel, about 250 deg. C., to the lowest temperatures obtainable with liquefied gases.

When the bulb is used as one arm of a Wheatstone bridge, the galvanometer employed will only give accurate indications when used as a null instrument, unless provision is made for supplying a constant emf, in which case it may be used as a deflection instrument. The form of indicator most commonly used

with the null method has a dial graduated to degrees under a pointer which moves a contact over an adjustable resistance.

Selection of Type of Pyrometer.

In the selection of the suitable type and form of instrument for measuring temperature under any particular conditions, the temperature range will be one of the first considerations. For temperatures with a maximum range above 1500 deg. C. (2732 deg. Fahr.), the radiation type is the only one of the three which is available. The lower limit for this type of instrument is ordinarily about 500 deg. C. (932 deg. Fahr.).

While the upper limit is 1500 deg. C. choice may be had between the radiation and the platinum thermocouple.

Where the upper range is 1200 deg. C. (2192 deg. Fahr.), the chrome-nickel thermocouple, the platinum thermocouple, and the radiation type may all be used.

For temperatures up to 1000 deg. C. (1832 deg. Fahr.), the iron-constantan thermocouple would come first in consideration, with the platinum resistance type also available.

For temperatures below 200 deg. C. (392 deg. Fahr.), the iron-constantan thermocouple and the nickel resistance could be employed, with the choice probably in favor of the resistance type.

The form and size of the thermocouple or resistance bulb would also be determined by circumstances. Where large heat areas are under consideration, with slow changes of temperature, the thermocouple may be of large cross-section, and thoroughly protected with iron or refractory tubes.

Where the bodies to be measured are small, and the temperature fluctuations are very rapid, the thermocouple must be made smaller. For example, if we are determining the transformation point of a number of specimens of steel, it is desirable that the specimens be small, with a small opening into which we may insert a very small thermocouple.

The same considerations which make the thermocouple small, would determine the choice of the thermocouple as against the resistance bulb, since the former can be made almost infinitesimally small, and will correspond with corresponding quickness to the temperature of the enclosing body.

Where thermocouples are used, the greatest consideration must be given to the matter of cold-end variation, and in the installation the most complete precaution must be taken in the matter of wiring, to make sure that all joints are permanently made.

In the case of resistance thermometers, the failure to get good results is often due to the failure to protect the lead wires from moisture or from abrasion. In fine, we must recognize that in general when making temperature measurements, we are handling a complex problem, and are dealing with electrical temperature-measuring devices which are sensitive instruments, requiring the application of judgment to obtain the best results.*

Philadelphia, Pa.

The South African Mining Journal recently celebrated its twenty-first anniversary by issuing a souvenir number. The issue contains historical data on Rand mining and milling, as well as a general survey of present conditions, and is in keeping with the importance of the special field covered.

The Yarnall-Waring Company, formerly at 1100 Locust street, Philadelphia, announces their removal to Chestnut Hill, Philadelphia, having assumed management of the factory and sales of the Nelson Valve Company. The identities of both companies will be maintained as before.

Electrical Show at University of Illinois.—An electrical show is to be held at the University of Illinois at Urbana, Illinois, on February 6, 7, and 8, 1913, under the auspices of the Electrical Engineering Society. This show is a triennial event and a university affair, conducted wholly by the undergraduate students, of interest to the alumni as well as to electric power users and manufacturers who will be allowed to exhibit.

*In connection with this subject the article by Dr. Northrup on the thermal e.m.f. of tungsten and molybdenum on page 45 of this issue will be found interesting.—EDITOR.

A New Type of Blast Furnace Construction

A paper read at the Cleveland meeting of the American Institute of Mining Engineers by J. E. Johnson, Jr.

The general construction of blast furnaces has undergone no radical change in more than a generation. When the old style of masonry construction was replaced by the steel shell, the masonry piers were simultaneously replaced by columns never less than six and frequently twelve or sixteen in number, set under the mantle ring. These columns were at first unvaryingly made of cast iron, but in more recent years have frequently been made of structural steel.

The furnace itself has recently been the subject of radical

changes; in some cases the thin-lined construction has been adopted for the whole furnace, and in other cases has been adopted for a zone immediately above the bosh, raising the mantle several feet to make this possible, but still the style of construction with columns set immediately under the mantle has been universally followed. In spite of the apparent permanence of this type of construction it is open to grave disadvantages from the operating point of view, which may be briefly outlined as follows:

The bustle pipe is necessarily outside the columns as the slope of the bosh and size of the crucible are such as to leave but little room inside the columns for the necessary water piping, etc., consequently the penstocks have to pass between the columns. Moreover, the hearth jacket requires a diameter but little smaller than the circle of the inside of the columns, and as a result the cooling-water ditch for protection against breakouts is exceedingly limited in width. As a consequence of these conditions, when any work requires to be done around the furnace such as changing a tuyere or working on the cooling-water pipes, the amount of room left by the columns, penstocks and water pipes is more conspicuous by its absence than by its presence. Moreover, if a break-out occurs, the ditch is filled with iron, perhaps half way around the furnace, or more. This locks itself in between the columns and the hearth jacket in a way that not infrequently makes impossible its removal while in blast. I knew one furnaceman who declared that the proper thing to do with the ditch was to run

the first cast of iron into it and let it stay there so as to save future bother.

Another result that not infrequently has followed break-outs is the burning and cracking of the columns by the molten iron and cinder surrounding them.

Still another result of this construction is less immediately disastrous, but leads eventually to a very serious condition. The space between the base of the columns and the hearth jacket being so small the whole structure is necessarily set

on one foundation and the continual expansion, which all masonry structures undergo from continued heating, gradually pushes the column bases out. In some cases an effort has been made to resist this tendency by making a continuous sole plate, or ring, on which the bases of the columns rested, but I have never known a case in which these were not broken and some plants have abandoned their use altogether, using simply an individual base under each column on the ground that as they will break apart anyway it makes a neater job to make them separate in the first place.

I think all furnacemen have experienced these

conditions and will agree to the general correctness of these objections to this construction.

It had seemed to me for several years that it would be possible to avoid these evils by building a frame-work of structural material strong enough to carry the weight of the whole furnace and supporting this on columns set at the corners of this frame-work, which would throw them so far back from the furnace proper that they would be safe from all danger from break-outs or other accidents, and at the same time would allow room enough around the furnace for necessary access to all parts with great safety, ease and speed in all necessary work; and that if the ditch became filled with iron, this would be unable to lock itself around the columns, and, being free on one side could readily be removed.

When our investigation concerning the quality of charcoal iron had indicated the desirability of reconstructing the fur-

FIG. 1.—NEW TYPE OF BLAST-FURNACE CONSTRUCTION.

nace to obtain the lines needed, we laid out various plans for doing the work and this construction appeared to be so practicable from an engineering standpoint, and so desirable from an operating standpoint, that it was finally adopted.

We first laid it out with the idea of using a triangular frame of girders with a column at each angle, and in order to get the girders above the bustle pipe we considered using the thin-lined construction for several feet above the bosh angle and letting the mantle at the top of this thin zone rest directly on the girders. This is shown in Fig. 2.

But on further consideration there were two features of this design which we did not like. We desired to use the steel bosh jacket construction, cooled by external sprays which

the crucible upward from the hearth, and consequently space must be allowed in which this expansion can take place without injury to the structure, without shearing off any water pipes, and in such a position that the crack formed by the expansion will be sealed by cinder as fast as formed. This thin skel on the bosh jacket is obviously unsuited to support any brick-work above it, and, while the lining is self-renewing on the sloping surface of the bosh jacket, we were fearful that this would not be the case on the vertical or overhanging section above the bosh. We, therefore, thought it best not to adopt the thin-lined zone above the bosh.

In regard to the three-column construction, while it sets the columns back further from the furnace than does the four-column construction, and while three columns are theoretically enough to support any structure, still in the event of a serious accident around the bottom of the furnace, it was conceivable, even though, I think, highly improbable, that one column might be sufficiently affected by heat to yield, and with the three-column construction this would throw the whole furnace to the ground.

With the four-column construction on the other hand, if anchor bolts to hold the structure down to the foundation were used, one column could fail completely and the two adjacent to it would carry the structure with the assistance of the counter-weighting action of the column opposite to the one that failed. This, of course, would only be true if the columns were made so strong that any two would carry the structure.

Accordingly, the four-column construction was adopted and the columns designed to have an ample factor of safety with any two of them supporting the entire weight.

In order to raise the girders above the bustle pipe and at the same time avoid the high mantle possible only with the thin-lined zone above the top of the bosh, it was necessary to support the shell on the girders by brackets. In order to reduce the local stresses on the bottom of the shell, due to these brackets, as far as possible, eight of them were used. This also had the great advantage that by spacing the brackets so that the centers of the girders came half way between them the load on the girders was applied relatively close to the columns and the bending movement enormously reduced. At the same time the distance from the shell to the center of bearing on the base of the brackets was increased but little over what it would have been had they come on the center of the columns.

It is obvious that the mantle plate would be entirely unsupported except at its outer edge and that it might deflect at the inner edge, owing to the weight of the brick-work, if some provision were not made to prevent this.

The extent to which this action could occur in view of the brick being so firmly supported at the outside by the heavy angle riveted to the shell, is problematical, but it was not desired to take any chances and a cantilever bracket was therefore designed to support the mantle plate from below to within a short distance of its inner edge.

The angles which are employed to rivet the bracket to the shell are continued down below the mantle and support a heavy vertical plate, the inner end of which projects under the mantle plate, while the outer end is prevented from rising under the weight so applied by heavy angles fastened to it, which pass up outside the girder and take hold of the outer end of the shell bracket. It is obvious that the angles next the shell act in tension and those outside the girder in compression, making a very rigid support for the overhanging end of the cantilever under the mantle plate. In order to prevent any possibility of deflection of the mantle plate between these brackets, heavy channels were riveted to the inner ends of the cantilevers in such a position that the center of the channel comes as close as desirable to the edge of the mantle plate. This forms an octagonal ring of heavy channels which also reinforce powerfully the inner ends of the cantilevers and make it impossible for them to fail by buckling.

FIG. 2—HORIZONTAL AND VERTICAL SECTION.

has proven so durable and satisfactory at many plants in the South and at some in the North, and which avoids entirely the stepped bosh wall, almost as angular and rough as a flight of steps, into which the cooling plate construction soon wears.

When the bosh jacket construction is used it is necessary to realize that no matter how much brick may be laid on the jacket at the beginning of the blast, it will all soon be gone, and its place taken by a combination of carbon, slag, etc., held on the slope of the jacket by the water cooling. When this construction is adopted provision must be made for the fact demonstrated by experience that the bosh will expand downward from the mantle on which it must be supported and

FIG. 3—BLAST FURNACE DESIGN.

The general construction is shown by Fig. 3. The section on the right hand side is taken through the center line of column and a tuyere and penstock are shown as if they lay in the same plane. As a matter of fact, they do not; the center lines of those tuyeres which come nearest to the columns pass a foot or two to the side of the columns and allow ample room for rodding the tuyeres. This section was made in this way to show the minimum of room around the furnace at any point. The left-hand section is on a plane at right angles to the girder, and while the column in that view looks comparatively close to the furnace, it is, of course, in reality at the distance shown on the right-hand side.

It will be seen that four independent piers of concrete were provided and that these set back at a great distance from the foundation of the hearth of the furnace proper. These piers are at such a distance from the foundation of the hearth and so entirely separated therefrom that it seems impossible there should ever be any transmission of the expansion of the hearth through the soft dirt between the two, which could force the piers out of position. Therefore, the columns should remain as built indefinitely.

It will be noticed that brackets were introduced between the top of the column and the bottom of the girder on each corner to prevent any possibility of the columns failing by leaning all in the same direction circumferentially. Across the corners of the main girders channels were riveted at top and bottom to form diagonal braces. These were latticed together vertically for greater strength, as shown in Fig. 4, which shows the structural work without the shell. The girders were so located that the inner edge of their flanges was 4 inches from the shell at the closest point, and the corner braces were put 7 inches from the shell at the closest point, thus leaving plenty of access to the shell for anything that may be necessary, even behind the girders.

The brackets are not riveted to the girders either at top or bottom. This is for the reason that if the bottom ring of the shell should give way in any manner and carry the brackets out, then if the latter were riveted to the girder this would put a bend in the top or compression flanges of the girders and might induce their failure. The girders and brackets not being riveted together, opportunity is provided for the bracket to slide on the girder and leave the latter undeformed under any possible condition. In addition the bottom

ring of the shell was made very strong to provide against this contingency.

The inward thrust at the top of the brackets comes on the seam uniting the bottom and second shell plates and throws this into compression. The proportions of the bracket are such that the inward reaction from each one is relatively slight and the probabilities are that the sheets alone would be able to resist it without deformation, but in order to leave no doubt whatever on this score, a heavy 6-inch angle was run entirely around inside the shell just at the bottom edge of the second sheet in such a position as to receive the full thrust from the brackets.

This being the first time this construction had ever been used, it was not considered desirable to leave undone anything that could contribute to additional safety or provide against possibility of failure in unlikely ways. The probabilities are that some of these extra provisions for strength could be left off without detriment, but it was not considered desirable to do so in this initial installation.

In regard to the strength of the girders, they were designed to be safe with a low unit-stress, assuming that the weight of the shell, top rigging and top house; lining, back lining, bustle pipe and the entire charge from the hearth to to the stock line were supported on them. This last condition is most unlikely, but it is conceivable that the furnace might become so badly scaffolded just above the tuyeres that the weight of the whole charge would come onto the mantle and so onto the structural work. We, therefore, provided against this contingency in the design.

The general appearance of the furnace in operation is well shown by the photograph, Fig. 1. Two men stood shoulder to shoulder as nearly in line as they could be placed between the wicket on the penstock and the nearest column, in order to show the amount of room available. In addition to this, as above stated, this tuyere is not in line radially with this column so that the access to the tuyeres is even more unrestricted than would be indicated by the photograph. This could have been made even better than it is except that the hot-blast main was so located as to prevent placing the columns four-square with the line of the tapping hole, which would have been better in several respects, but we did not desire to disturb the hot-blast main and shifted the columns a foot or two to the left to miss it. It will be seen that the columns are bricked up to a height of 6 feet to prevent any possibility of damage to them by fire. We considered also making provision to keep them filled with waste water for several feet up, but this was not considered necessary. The brick-work surrounding them is hard fire-brick laid in cement and almost indestructible.

The accessibility of the furnace for work of any kind is remarkable and I do not think that anyone who had worked around a furnace of this design would ever desire to return to the old type of construction.

It will be noticed in Fig. 3 that the outside wall of the ditch is merely $4\frac{1}{2}$ inches of brick. We had some trouble with the cinder cooler on one occasion since the furnace was blown in and got quite a little iron into the ditch beneath it. It ran around the furnace a distance of 7 or 8 feet. This would have been sufficient to tie itself in behind one or more columns with the old construction and would have been very difficult to get out. As it was, we simply tore down the $4\frac{1}{2}$ -inch wall from the outside of the ditch, pulled the "chunk" away from the hearth-jacket, out of the ditch, in one piece and replaced the $4\frac{1}{2}$ inch wall. This accessibility is also a great advantage in working at water pipes, and, especially in following these from the cocks on the circle pipe to the cooling member that they supply.

The very short and direct connection from the bustle pipe to the tuyeres is shown both by Fig. 2 and by the photograph. In fact the bustle pipe is almost too close to the bosh wall for greatest convenience. It is obvious that there is ample room to increase its circle and provide more room if it were ever desired to do so.

Objection will probably be made to this construction on the ground of cost, but the great saving in real cost over the standard construction is one of the features which pleased us most. The first cost of the four-column construction was less than \$2,000 in excess of that of the standard construction, but of this saving about \$1,000 would have been wiped out by the cost of work on the bustle pipe had we adopted the old construction for the following reason.

In order to have gotten the furnace lines desired with the standard construction we would have had either to provide a new bustle pipe complete or cut the present one down, cut it in two in six places and insert rings to increase its diameter and reline it complete, which could scarcely have been done for a thousand dollars. The actual money cost was, therefore, a few hundred dollars greater for the four-column construction than for the standard, but we have to consider also the element of time.

Owing to the location of the foundations for the new columns, one of these was put in before the old furnace was blown out. A second one could have been had we known

FIG. 4—SUPPORT FOR BLAST FURNACE

more accurately the location of the waste water sewer, but this and the two front ones were actually put in immediately after the furnace blew out and they were done before the work of tearing down the old furnace had progressed very far. Of course, if the standard construction had been employed the old columns would have had to be removed and the whole foundation exposed before the new foundation could be added. As it was, not only the foundations were built but the structural work for the new furnace was erected by the time the bosh and the upper part of the lining of the old furnace had been torn out. We estimate a saving of from two to three weeks in time on this account alone.

When the steel bosh jacket is used with the ordinary type of furnace it has necessarily to be fitted up and riveted together in several sections inside the columns, and, in fact, it is commonly attached to the edge of the mantle ring as it is put together with the necessity of a great deal of fitting of the vertical seams. In the present instance the bosh jacket was built entirely independent of the furnace and when the construction had advanced far enough to receive it, it was simply shoved in through the columns, hoisted up to place and riveted fast, the entire job taking only about two days as against two or three weeks that would have been required had it been built up in place in the customary way.*

We consider that we made easily a saving of five weeks on these two accounts alone. The loss of profits, overhead

*A paper read at the Cleveland meeting of the American Institute of Mining Engineers.

charges, etc., at such a plant can not be estimated at less than \$500 a day, and this saving of thirty-five days, therefore, represents a saving of \$17,500, or deducting \$1,000 for the excess cost over the standard construction, a net saving by the use of this construction of \$16,500.

It is customary to regard charcoal furnaces as insignificant in size, but this furnace is 60 feet high and of a size that would make from 200 to 300 tons per day with moderate driving on coke iron. Furnaces have such an enormous capacity for exerting destructive energy that the tendency in the minds familiar with them is to overestimate their actual weight. It is doubtful if the weight of a large coke furnace figured on the basis above described would exceed 2,000 tons, and there is no difficulty whatever in carrying a load of this amount with a construction of this kind.

It may be well to point out that this construction lends itself particularly well to the thin-lined type of furnace because the weight of the lining in such a furnace is an insignificant fraction of that of a standard thick lining, and because some outside structure is generally necessary for supporting the platforms, spray apparatus, etc., even if not the furnace top proper. This can all be done with great advantage from the girder frame if the type of construction here described be used.

It is well to point out also that if the cooling-plate construction of the hearth be used so as to form an adequate support for a thin lining in the zone immediately above the bosh, then the high mantle, which results from that construction, may be directly supported on the girders about as shown in Fig. 1. Methods can also be devised without difficulty for supporting the lining of the thin zone with the steel bosh jacket construction by providing a narrow water-cooled false mantle at the bosh angle, but we did not consider this construction necessary for our conditions.

CONCLUSIONS.

1. A furnace designed on the plan described is not only feasible but a safe and substantial construction.

2. This construction is especially well adapted to the thin-lined, or partly thin-lined furnace.

3. Its convenience in operation is so much greater than that of the older type of furnace that there is no comparison from an operating point of view.

4. The time to be saved by the use of this construction, at least in rebuilding, is so great as to constitute a money saving of far greater extent than the slight excess cost of this construction over the standard.

Roasting and Drying Furnaces.—The Ridge Roasting Furnace and Engineering Company, 62 London Wall, London, E. C., has been formed to take over the patents of Mr. H. M. Ridge for roasting, calcining and drying furnaces.

Identification of Tellurides.—In a study of the tellurides of Kalgoorlie, published in the September *Journal of the Chamber of Mines of Western Australia*, J. Allan Thomson gives the following tests of identification: The presence of tellurium may easily be detected by blow-pipe tests. When heated on charcoal in the oxidizing flame, all the gold, silver, lead and mercury tellurides quickly fuse and emit dense white fumes of characteristic odor. They coat the charcoal with white TeO_2 . When the bead is touched with the reducing flame it imparts to it a bright bluish green color. When heated in a closed tube the tellurides again form white TeO_2 . This fuses on further heating to a liquid which is yellow when hot and white when cold. Sometimes a black sublimate of metallic tellurium is obtained. A simple wet test is to heat a fragment of the mineral on a porcelain plate and allow a few drops of sulphuric acid to flow over it.

Recent Progress in Electrolytic Process for Zinc.

Dr. Victor Engelhardt, the well-known chief engineer of the electrochemical department of the Siemens & Halske Company, delivered a lecture on electrolytic zinc processes at the recent first general meeting of the Gesellschaft Deutscher Metallhütten und Bergleute. Although Dr. Engelhardt is lecturing on electric furnaces at the new Institute of Technology in Breslau, he is more particularly familiar with electrolytic practice from large-scale work. The following is an abstract from his interesting paper:

The world's production of zinc, as taken from *Mineral Industry*, amounted to 815,097 metric tons in 1910, of which probably not more than 10,000 to 15,000 or 1.2 to 2 per cent were used as a high-grade metal of special purity. Zinc of 99.98 per cent purity is not much in demand, except for laboratory use and for making special pure brasses for use in cold drawing and pressing work such as are needed for cartridges, etc. This fact has held back the development of electrolytic zinc processes, especially as three considerable technical difficulties had to be overcome, viz., the difficulty of the design of suitable apparatus, the high-power consumption per unit of metal, and the fact that the zinc is liable to be deposited in spongy form.

Since there is little commercial use for high-grade electrolytic zinc at a higher price than ordinary zinc commands, the electrolytic process must be able to compete with the present marketable product. This, the author points out, is now possible under certain conditions.

He first reviews the older work in this line by briefly characterizing the main types of different processes which have been tried or suggested, without going into details of the enormous mass of patent literature.

I. Refining.

(a) *Anodes without precious metal.*—The mere refining of commercial zinc, analogous to copper refining, is economically absurd.

(b) *Anodes with precious metals.*—The refining of the ZnAg alloy, obtained from the desilverization of lead, with up to 10 per cent Ag, did not prove cheap enough and was apparently abandoned before the technical details could have been worked out.

II. Direct Processes.

(a) *With soluble anodes containing zinc.*—In order to utilize the energy due to the solution of the anode a great many attempts have been made since 1880 to prepare anodes containing various zinc compounds, mixed with coke or coal powder with and without pressure, with various binding materials, etc. They all must be recorded as failures as was the case with the analogous Marchese process in which it was tried to use copper ores or intermediate copper smelter products as anodes for direct production of copper.

(b) *With soluble anodes free from zinc.*—The patents of Cassel and Kjellin of 1892 started a series of equally unsuccessful experiments with diaphragm cells and anodes of iron in ferrous-sulphate solution or of lead in zinc chloride. Iron will soon contaminate the cathode electrolyte, and other trials gave no better results.

(c) *With non-soluble anodes and utilization of the anode energy.*—In two processes of Siemens & Halske, in 1880 and 1890, an attempt was made to use an electrolyte which would leach the sulfide or oxide ore and which would then be passed through an electrolytic cell where the metal would be deposited on the cathode, while the solution was regenerated at the anode. Both processes are merely of historical interest to-day.

The first process is represented by the two equations:

The second one by:

The basic aluminum sulfate was, however, partly decom-

posed during the leaching process and an integral part of the electrolyte was thereby lost.

(d) *With insoluble anodes and without utilization of the anodic energy.*—Processes of this group are the only ones which have reached the commercial stage. A typical example of $ZnCl_2$ electrolysis is the Hoepfner process, a typical example of $ZnSO_4$ electrolysis the Siemens-Halske process. The plants installed by Hoepfner in Germany, England and Austria are no longer in operation.

Hoepfner started from a cheap raw material, pyrite residues with about 10 per cent Zn, mostly as ZnS , which had to be subjected to a chloridizing roasting with subsequent leaching, freezing out of the Na_2SO_4 , oxidation with hypochlorite of lime and precipitation, first by carbonate of lime, then by zinc dust. The purified solution was electrolyzed in a diaphragm cell with carbon anodes, and rotating cathodes of zinc or iron. The zinc produced by this process was of good quality, but the complexity of operation and apparatus and the necessity of collecting several by-products which were hitherto foreign to metallurgical plants and for which a market had to be found were serious objections.

The sulfate electrolyte affords simpler conditions in many respects. One point requiring the most careful attention in both cases is to avoid the formation of spongy metal. The cathodic zinc deposit cathode is not smooth enough for immediate rolling. The trade demands for alloying purposes small and easily detachable units. The electrolytic deposit is therefore molten and cast into forms of the customary shape. But when this is done, spongy metal oxidizes and is completely lost.

This problem is the most vital point of the whole process and decides on success or failure. The deposition of the purest possible zinc is therefore absolutely necessary. This is better attained in the Siemens-Halske sulfate process since the latter dispenses with diaphragms and rotating electrodes. The solution is purified in the same way as by Hoepfner, without requiring the removal of sodium sulfate. For economic reasons the accumulation of free sulfuric acid by reaction at the anode is carried on as far as the quality of the metal will allow. If it becomes too high, the danger of impurities in the cathode and of formation of spongy metal becomes imminent.

Lead Peroxide and Manganese Peroxide Anodes

The latest progress made by the Siemens-Halske Company relates to the manufacture of suitable anodes. Acheson graphite, the best anode for electrolysis of chlorides of alkalis and of zinc chloride, is corroded by sulfuric acid, platinum is too expensive and partly soluble, and the coating of PbO_2 formed on lead electrodes is not sufficiently coherent to prevent formation and dissolving of lead sulfate.

The invention of Dr. Ferchland, offered to the Siemens & Halske Company seven years ago, concerning the electrolytic formation of PbO_2 electrodes has been improved and perfected and is now in commercial use. PbO_2 is precipitated on anodes of carbon tubes (an addition of colloids permitting to produce a smooth deposit) and the carbon bored out afterward. Several of these lead peroxide tubes are held and connected together in parallel by a lead casting.

These anodes have been used in a small plant in Lipine, Silesia, Germany, where roasted upper Silesian blende is treated and smooth and thick plates of the following purity are produced

	From			From
	Silesian Blende			Refractory Ores.
Pb	0.019	0.028	0.013	0.014
Fe	0.015	0.017	0.003	0.018
Mn, As, etc.				trace
Zn (difference)	0.006	0.005	0.004	0.006

The ampere-hour efficiency was 80 per cent at 3.8 volts per cell. The specific power consumption was, therefore, not quite 4 kw-hours per kilogram of zinc. The loss in melting was 3

per cent. The ductility of the zinc effected a 10 per cent production in the cost of rolling.

Whereas in this case the cost of the anodes ran up to 70 marks per ton of metal (\$16 per 2000 lb.), the company succeeded quite recently, through the efforts of Dr. Max Huth, to reduce the anode cost to one-seventh. He tried to prepare anodes in the shape of plates and is now able to produce them from manganese peroxide, held in a carbon contact piece. The life of these anodes in commercial practice is estimated as about one year. Details of their manufacture are not revealed.

The power consumption has been reduced to 3.4 kw-hours per kilogram Zn, while chloride electrolysis requires 4.2 kw-hours for continuous operation.

Large experimental plants have been erected on this basis in England and in the United States, while the erection of a big commercial plant is projected.

The leaching of the ores which was done in Lipine in open stirring tanks is carried out in England and the United States by a special process of Dr. Isherwood, who uses an insufficient amount of sulfuric acid under pressure and thus obtains purer solutions from the start.

We omit Dr. Engelhardt's calculation of the operating costs as differing too widely under varying conditions. It will be sufficient to say that cheap ore, preferably such ores as will be less suitable for reduction in the muffle, and cheap water power are the main requirements for the new process. At marks 222 per ton of zinc in the ore, the power would have to cost 2.5 pfennigs or 0.6 cent per kw-hour in order to just cover the manufacturing cost with the market price.

The interesting discussion of the paper by Dr. Hans Goldschmidt revealed the fact, that the low loss in melting the cathodes results from dipping the cathodes into molten zinc and excluding the air to the greatest possible extent.

The complete paper is published in *Metall und Erz*, Vol. 10, p. 60-72, 1912.

British Salt Trade.

An increase in the number of salt works on the Cheshire side of the Ship Canal is expected as a consequence of the establishment of the right to pump brine; and at Lymn the existence of very large salt deposits has been ascertained. The Castner-Kellner Alkali Works, at Runcorn, draw brine from the Marbury pipe, and extensive operations are expected to be undertaken shortly on the Heatley estate, which has a long frontage on the canal. The result of borings made near Heatley Station is asserted to show the existence of a thick bed of rock salt on the estate.

British Engineering Imports and Exports.

The returns issued by the Board of Trade for the nine months ended on Sept. 30 show considerable increases in the value of both imports and exports of engineering material—imports of ships excepted—as compared with the corresponding period of last year. Imports of iron and steel, including manufactures, totaled £9,232,320, an increase of £1,031,046, and exports were £34,549,271, an increase of £2,697,070. In other metals, including manufactures, imports reached £22,230,943, an increase of £1,500,064, while exports touched £8,684,345, an increase of £659,384. Imports of electrical goods went up to £1,036,376, increasing £23,733, and exports figured at £3,198,770, a rise of £1,207,918. Imports of machinery amounted to £4,995,839, an improvement of £584,181, and exports moved to £24,056,385, a rise of £1,520,443. For new ships the imports were £25,308, a decline of £35,608, but exports rose to £4,433,042, an improvement of £393,560.

Taking the month of September by itself, imports and exports of iron and steel showed, respectively, increases of £338,493 and £1,405,816; in other metals imports fell £233,210 and exports rose £232,717; imports and exports of machinery rose £62,033 and £756,186, respectively; in electrical goods imports dropped £10,859, but exports were £277,024 better; imports of new ships were £3,719 lower, and exports improved £384,792.

Tungsten and Molybdenum—Their Thermal Emf.

By Edwin F. Northrup, Ph.D.

The writer suggested at a recent meeting of the Philadelphia local branch of the American Institute of Electrical Engineers, that the possibilities for further developments are greater in thermocouple pyrometry than they are in electrical resistance pyrometry. He remarked that possibly tungsten and molybdenum might be used at high temperatures for a thermocouple and that although these metals oxidize at high temperatures, it might be possible to avoid oxidation by the use of some kind of protecting covering.

In reply to these statements it was remarked by a manufacturer of pyrometers that the writer's suggestion seemed to be an excellent one, with one exception, namely, that between tungsten and molybdenum there exists *no* thermal emf. The speaker said he knew because he had experimentally tested the truth of his statement.

The writer was silenced because he had not at the time tested the property in question of these two metals. He was not,

E. M. F.—TEMPERATURE CURVE OF TUNGSTEN-MOLYBDENUM THERMOCOUPLE.

however, convinced and later through the kindness of Dr. W. R. Whitney, of the Research Laboratory, of the General Electric Company, he was able to obtain a wire of tungsten and a wire of molybdenum, each about No. 20 B. & S. gauge. With the furnace at his disposal he was able to determine the curve relating emf to temperature in the range 0 deg. C. to 1000 deg. C. The curve obtained is given in the accompanying diagram.

The emf's were measured with a Leeds and Northrup potentiometer and the temperature was measured by measuring the emf developed by a platinum, platinum plus 10 per cent rhodium thermocouple. This thermocouple was accompanied by a certificate from the Bureau of Standards.

The following points may be mentioned:

The equation,

$E = 4.61t - 0.00436t^2$ microvolts fits the curve in the range from 0 to 1000 deg. C. with an error of less than 4 per cent.

When the cold junction is at 0 deg. C. the emf is a maximum at 530 deg. C. and is 0 at 1060 deg. C., which, within the limits of error of the experiment, is the melting point of gold (1062 deg. C.). The current in this range flows from tungsten to molybdenum through the hot junction. The thermal emf. is sufficiently high at 300 deg. C. or at 750 deg. C. to be measured on the potentiometer used within 0.2 of 1 per cent.

If the law of the thermal emf as given by the equation continues to hold to a temperature of 2300 deg. C. the thermal emf would be at this temperature, when the cold junction is at 0 deg. C., 10,960 microvolts or about 11 millivolts—an easily measured emf. The molybdenum would then, of course, be positive to tungsten at the hot junction.

It is very desirable that many samples of tungsten and molybdenum be tested in the above manner. If they all have a neutral point at the same temperature, namely, at 1060 deg. C., then

a thermocouple of these metals would serve in a very convenient way to fix this temperature. A couple or a resistance thermometer to be tested would be put in the same electric oven with the tungsten molybdenum couple and the temperature raised until the latter showed zero emf. The temperature would then be 1060 deg. C.

The writer does not think that there is no hope of finding a protecting case for the couple at 2000 deg. C. or more. At 100 deg. C. the oxidation is negligible and for laboratory work it could be prevented in most cases for higher temperatures by employing a non-oxidizing gas.

Princeton, N. J.*

Some Present Pickling Methods.

By Oliver W. Storey.

In the hot working of iron, steel and cast iron, the unavoidable formation of a scale makes the subsequent operation of pickling necessary, especially in the various galvanizing, plating and enameling processes. This scale consists essentially of the magnetic oxide of iron, which is resistant to corrosive action.

Ordinary mill scale, as found on hot-worked materials, is present in various thicknesses. On black sheets it is present as a thin coating, while on heavy rolled shapes it is much thicker, often being over 1/32" in thickness. The coating especially when heavy is usually porous and brittle, while more flexible and continuous when thin.

The resistance of a certain quality of iron oxide to corrosive action is the basis of the protective coatings of the Bauer-Barff and Wells processes. By these methods a thin continuous coating of the magnetic oxide is produced on the surface of the iron and the article is rendered immune to corrosion as long as the continuity of the coating is not broken. Since the magnetic oxide is electronegative to iron by nearly two volts, the damaging of the surface will start a rapid electrochemical corrosion of the iron base.

For ease in removing scale by pickling a continuous coating of the magnetic oxide is undesirable since it is insoluble in the pickling acid and prevents the action on the underlying iron. It is well known that the principal function of the pickling acid is not dissolving the scale but the dissolving of the underlying iron sufficiently to loosen the scale. Scale formed under ordinary hot working conditions is porous and is usually easily removed.

If all the scale found on iron and steel were pure magnetic oxide, the problem of pickling would not be as troublesome as it is at present. Not only does the thickness of the scale vary, but its composition varies owing to impurities. Ordinary black sheets do not always present a smooth surface but often are very rough. It will be found that cinder, slag and scale contained in these rough places cause trouble in pickling. Since a much longer time is required to remove the scale from these rough spots the rest of the surface will be overpickled and the cleaned iron will present an uneven surface. Similar troubles are found in the pickling of iron pipe. Forged material is especially difficult to pickle owing to the cinder and scale that is driven into the iron.

Acids Used for Pickling.

The acids usually used for pickling are sulphuric, hydrochloric and hydrofluoric. The last is frequently used on castings to dissolve any adhering sand that may be in a position where it cannot be easily removed by tumbling or sand blasting. Sulphuric acid is the one almost universally used for pickling purposes. This is owing to its cheapness and ease of transportation in large quantities by tank cars. Sixty deg. and 66 deg. Be. acid is worth from \$6c. to 8c. a hundred f.o.b. plant in most industrial districts, this price holding for a brimstone acid containing a minimum of arsenic. The sulphuric acid must have high purity since certain impurities will cut down the pickling power. Arsenic especially is most undesirable as an exceedingly small quantity is harmful.

Prof. C. F. Burgess was among the first to show the quantitative relation between the arsenic content of sulphuric acid to its pickling power and to give an explanation of this phenomenon.¹ It had been known in general for over sixty years that the presence of arsenic in sulphuric acid was detrimental when used for pickling purposes, but no definite work had been done or had any explanation been offered.

Dr. O. P. Watts has elaborated on this work and the influence of various materials on the rate of corrosion of iron has been investigated in the Chemical Engineering Laboratories of the University of Wisconsin and some interesting results obtained.² These results show that arsenic is an effective retarder of corrosion and the same is true of tin. Lead, which is soluble to a slight extent in sulphuric acid, is also a retarder. While certain materials are more or less effective in retarding corrosion, others may cause accelerated action.

It would appear that a mixture of acids, such as sulphuric and hydrochloric, ought to cause an accelerated rate of corrosion, but the results show a high rate of retardation.

These experiments indicate that the acids used for pickling purposes must be free from those materials that retard corrosion to be able to secure a maximum pickling efficiency. A small amount of these retarding materials present in the acid will often cut the capacity of the pickling plant in two and perhaps double the acid cost. A study of the action of sulphites and of selenium on the corrosion rate would be of importance, since these are also usually present in varying quantities in commercial acid. In fact, the whole question of the influence of impurities as to their influence on efficiency of pickling is worthy of further investigation.

Where large quantities of the acid are used it is bought in car-load lots and stored in large iron containers. If the acid has to be transported and stored in glass carboys it adds materially to the cost, owing to the large amount of handling during transportation, higher freight charges owing to freight classification, breakage of carboys and the danger in handling glass containers of acid.

The layout of a pickling plant depends on several factors, these being principally the character of the material to be pickled, capacity required, and the relation of the pickling process to the rest of the plant.

The character of material is of utmost importance as the various grades of iron, steel, and cast iron corrode at widely varying rates, the rate depending upon the kind of acid and the purity of the iron.³ In general, the lower the carbon content of the iron the lower the corrosion rate in materials subjected to the same heat treatment.

Pickling of Black Steel Sheets.

Probably the two materials that are most frequently pickled are black steel sheets and wrought iron and steel pipe, including both water pipe and conduit. Steel sheets are usually covered with a thin scale that can be easily removed, while the scale usually found on pipe is more difficult to remove owing to its weight. The methods used for pickling these materials will be taken up in detail.

To operate a pickling plant successfully requires a large supply of hot and cold water. A large amount of water is needed for washing after pickling to remove all traces of acids and metallic salts.

The pickling of black sheets is usually done with the so-called pickling machines. Such machines are now on the market capable of handling the material rapidly and economically, a typical one in general use being the Mesta pickling machine.* It consists essentially of a vertical plunger working in a cylinder, with three arms 120 deg. apart at the top of the plunger which is worked by steam or compressed air. Two vats are required with this type of machine; one acid and the other water. While one crate of sheets on the first arm is pickling in the first vat, the second crate on the second arm is being

washed in water, while the third is being unloaded or re-loaded. If a third vat is necessary the machine can be built with four arms.

The vats are constructed to the dimensions required by the material to be pickled. The crates are often made of wood but more often of some acid-resisting alloy. Where wood is employed nails or bolts of copper are necessary. The sheets are rested on edge in this crate, which is usually large enough to hold from 1500 to 2000 lb. of the material.

When sulphuric acid is used the strength of the solution usually varies from 3 to 8 per cent, and it is usually kept as near boiling as possible by injecting live steam into the vat. The high temperature has a remarkable effect on the rapidity and efficiency of the action. The sheets are forced apart to secure complete pickling by violently agitating the acid solution. With suitable agitation and separation of the sheets, this process may be completed in six to 10 minutes with a 6 per cent pickle. When a weak pickle, such as a 3 per cent solution and a temperature of about 180 deg. Fahr. is used, the sheets usually require about 30 minutes for complete removal of scale.

After being pickled they are transferred to the washing tank where the acid and ferrous salts are removed as completely as possible by copious supplies of fresh water. If the wash water is hot the sheets will dry quickly when brought into the air with the formation of but a negligible quantity of iron oxide. If the sheets are not for immediate use and are to be stored or shipped they are dipped in a lime or soda solution to kill any acid that may be present and prevent the formation of rust.

This method of pickling will remove all of the scale, but owing to the short period in the acid will not remove any cinder that may have been rolled into the surface of the sheet. If the sheet remains in the acid a greater length of time, the acid may attack enough of the iron to precipitate out a black deposit of carbon or some form of combined carbon that may cause trouble in later processes. Therefore, the sheets stay in the acid the minimum length of time required to remove the ordinary mill scale. About 140 lb. of 66-deg. acid is required per ton of sheets, though this of course varies with the thickness and other characteristics of the material.

Pickling of Pipe.

In the pickling of steel and wrought-iron pipe a different method is in use. For ordinary galvanizing purposes only the exterior of a pipe needs to be entirely free of scale in contrast with pipe for conduit purposes, where both interior and exterior have to be cleaned.

Vats are made the requisite length, 4 ft. to 6 ft. wide, and from 2 ft. to 3 ft. deep. The acid bath, the strength of which varies from 3 to 10 per cent of sulphuric acid, is heated by means of injected steam. The pipes are held in two acid-proof chains and at short intervals of time they are tumbled over each other by working these chains.⁵ This operation is repeated several times during the pickling period. The tumbling of the material is necessary for several reasons. It circulates the bath, especially in the interior of the pipe and it helps loosen some of the tougher scale of the exterior by abrasion and it also washes away the detached scale. When the exterior is sufficiently clear of scale the pipes are washed in water, as with sheets, and if they are to be hot galvanized, they are dipped into a hydrochloric acid solution. Upon removal the iron chloride formed is allowed to dry and acts as a flux in the galvanizing bath.

The pickling of pipe for conduit purposes presents a different problem. There are two methods in use for giving conduit a protective coating, enameling and galvanizing. Galvanizing may be hot, wet or electro, and dry or sherardizing. The same general method of pickling with sulphuric acid is used. Conduit pipe is 10 ft. long and must be thoroughly cleaned on the interior and exterior. Any scale remaining on the inside of conduit pipe will be a sufficient cause for its rejection by the Board of Underwriters, whose requirements are rigid.

⁴Metallurgical and Chemical Engineering, Vol. 8, No. 10, p. 598.

Before entering on the description of methods used for pickling conduit pipe it will be necessary to describe the scale found on the interior and exterior of the pipe. This will necessarily require a brief description of the methods of manufacture.

Conduit pipe is butt welded. The skelp is heated in a furnace whose bottom is usually lined with silica. At the temperature of the furnace the acid silica and basic iron oxide unite to form one of the easily fusible silicates of iron. When the skelp is withdrawn from the furnace it is drawn into the forming die so that the bottom of the skelp will come in the inside of the pipe. The silicate slag will therefore be found on the interior of the conduit. This silicate then runs to the bottom of the conduit and solidifies as a strip of hard glassy slag that adheres quite firmly to the iron. It has been suggested that the upper part of the skelp be turned in, but owing to the rapidity with which the silicate slag ruins the dies this is never practiced. This silicate slag is the cause of the trouble that is encountered in pickling pipe.

Since the interior of conduit pipe must be free from scale it presents difficulties that are not present when ordinary pipe is treated. The acid in the interior must be kept in circulation so as to have the rate of pickling as fast on the interior as on the exterior. Various methods have been tried, of which the more successful may be described.

Pickling on end is a natural method to suggest, the material being hung on racks and lowered into the acid vats. The hydrogen liberated on the interior of the pipe and rising to the surface creates a circulation of the acid bath. This method is effectual but it is open to several objections. The hanging of the material on the racks requires an extra operation and the same is true in taking the material down. The racks occupy a large space for a given number of pipe and the space required for the pickling plant is large. Large hoists are required for the lifting of material over a distance of at least 11 ft. Should the drainage sewers be down at the ordinary distance of about 6 ft. and it is required that the waste liquor run into them, it will be seen that the tanks will have to be elevated some distance to procure proper drainage. If any break should occur in the hoisting apparatus, a fall of 11 ft. to 12 ft. of the heavily loaded racks would probably be fatal to the pickling tank. The tanks would not be adapted for the pickling of other classes of materials.

The other methods of pickling consist of treating the conduit in a horizontal position instead of vertical. In this way the layout of the plant will be simpler since the tanks will be from 2 ft. to 3 ft. deep, 4 ft. wide and 11 ft. long. The material is laid in a cradle arrangement, the couplings on the one end of the pipe causing them to be completely separated and allowing the entire surface to be subject to the acid attack. This method allows of large quantities of pipe to be pickled in one vat. The methods used for getting a good circulation of acid in horizontal tanks differ.

The intermittent method is one in which the circulation is secured in the following manner: At certain intervals of about every fifteen or twenty minutes the racks or cradles of pipe are lifted from the tanks so that the pipes are at an angle with the horizontal, allowing them to drain easily. By plunging the rack up and down in the acid several times the loose scale and dirt are removed from the interior and the pickling is again allowed to proceed. This method is especially satisfactory where a weak pickle is used.

Another method of securing circulation is to have the pipe lay in a rocking cradle working in the acid. This secures excellent circulation, but it is open to the objection that it requires machinery to be present in a pickle room and in the bath where deterioration is rapid. By introducing paddle wheels, propellers and plungers, into the vats, circulation has been secured, but none of the methods given seem to give entire satisfaction.

In the treatment of conduit, the time of pickling is judged by the interior appearance. The exterior may become free from scale in a short time, but the interior may still contain a large amount. The conduit must remain in the pickle until all of this

scale is removed or until the iron surface or screw threads become visibly corroded. When this happens the pipe must be removed from the pickle to avoid being scrapped and the remaining scale must be sand blasted or otherwise removed from the interior.

Where the pipe contains the hard ridge of iron silicate, ordinary pickling and sand blasting will not entirely remove it, and the remainder is generally left in the interior of the pipe. Such a rigid scale is detrimental since it makes fishing difficult and is liable to cut the insulation of the fished wire.

If the pipe is to be used for cold galvanizing purposes it is washed with cold water after removing from the pickle. It may be dipped in cold dilute hydrochloric acid and then taken directly to the plating tank to prevent any oxide from being formed. If the pipe is to be sherardized, it is dipped into hot water to remove the acid and iron salts, then into a lime water and finally into a hot-water bath. Upon removing from the hot water the pipe dries quickly and a minimum of iron oxide is formed. This small amount of oxide is not detrimental, but, in fact, appears to give a brighter coating. If the pipe is to be enameled it is treated in the same manner as is the sherardized material.

Strength and Temperature of Pickle and Other Details.

The strength of the pickle varies a great deal, running from 3 to 8 per cent sulphuric acid. These various strengths have their advantages and disadvantages. When a 3 per cent solution is used a larger plant is required. This is offset by the various other advantages gained. When a 3 per cent solution, at a temperature of about 170 deg. Fahr., is used the rate of pickling is slow, requiring from three to twenty-four hours to pickle ordinary pipe. With this slow rate pipe will not be easily over-pickled if it should be accidentally left in the pickle too long. The slow rate of hydrogen liberation lessens the amount of finely divided acid thrown into the air and makes it easier upon the workmen and also upon the buildings and machinery. It is also possible to "kill" a low percentage bath until almost free from acid and this prevents any acid being run into the drains. With high-percentage acid baths it is customary to "kill" a bath to a certain percentage and then run it off as waste. The high-percentage bath is also harder upon the workmen. With a low-percentage pickle the amount of acid used per ton of pipe is much less than with a high-percentage pickle, usually running below 80 lb. per ton.

The temperature of the pickle is also very important, since the higher the temperature of the bath the faster the pickling. For most purposes it is best to have a boiling bath because it not alone produces a bigger tonnage, but it also removes all grease from the article to be pickled. With a boiling pickle, however, large volumes of acidulated steam are given off, with attendant corrosion of machinery, buildings, and the bad effect upon workmen.

The pickle is run until the action becomes too slow, when more acid is added. When a solution becomes concentrated with ferrous sulphate, the pickle is "killed" and then is generally run off as waste. The concentration in ferrous sulphate when "killed" varies a great deal, standing from 12 to 25 per cent, depending upon the practice at the plant.

Few plants attempt to utilize the ferrous salts and sulphuric acid in the waste pickle, since no satisfactory method has been offered. Its utilization has been made subject of a large number of patents. One of the most recent is that of F. F. Farnham, who electrolyzes the solution and obtains iron and sulphuric acid.⁶ Where utilization is practiced a common method is to neutralize the free acid by means of iron scrap, evaporating and crystallizing the iron salts, producing the copperas of commerce. This copperas has various uses, such as the making of various shades of red pigments, Indian red and Venetian red. Recent advocacy by agricultural experiment stations of this material as a weed killer has increased the outlet for it, but with all of the uses proposed, a general recovery from all spent liquors would undoubtedly flood the market.

⁶F. F. Farnham, Patent No. 1,006,836, Metallurgical and Chemical Engineering, 9/12/1911, p. 67 O.

In galvanizing and sherardizing plants, where the zinc sometimes has to be stripped from the iron, owing to defects and other causes, an old pickle is usually used for stripping the zinc and is found to work best. The potential of iron is below that of zinc and naturally the iron in the pickle as ferrous sulphate has a tendency to plate out and remove the zinc, though little acid is present.

Air hoists are generally used in pickling rooms owing to their simplicity, ease of operation and low cost of upkeep. Though compressed air as a source of power is costly, the other advantages gained by the use of compressed air counterbalance this factor.

Large and non-corrosive drains should be provided to take care of large amounts of water and killed acid. The best floors for pickling rooms are made of the iron scale that is deposited in the bottom of pickling tanks. This material is porous, is not attacked by acids, cheap and easily laid. Cement and concrete will quickly disintegrate and are therefore not available.

Another use found for the scale and sludge deposited in the bottom of the pickling vats is for the stopping of leaks in these vats.

By merely plastering this sludge into the leaky part the leak may be easily and effectually stopped.

This paper does not attempt to give all methods in use, but rather to describe what may be considered as general practice in pipe and sheet pickling at the present date. Pickling is a branch in the metallurgy of iron and steel that is open to a large amount of improvement. Mechanical treatment and cleaning of the materials has often been tried, but sulphuric acid treatment seems most satisfactory. Pickling plants are run more or less on hit-and-miss methods and the only improvements that have been made are in the mechanical end. The fault does not lie entirely with the chemical end of the industry for improvements may be made in the hot working of the metal so as to give a product of a kind that can be more easily pickled.

The ideal condition will be where the scale would be entirely soluble in some solvent while the iron would be insoluble. Since this is probably impossible, it would be well to obtain a condition where a minimum of scale is formed and in this way requiring but a short acid attack, resulting in minimum corrosion of the iron base.

Viewing the operation from a scientific standpoint the pickling process seems to be the application of "main force and awkwardness." The object is to present a clean iron surface, and this is done not by dissolving or otherwise eliminating the coating, but by dissolving away the iron surface itself. There is here an economic loss, not only in the mill scale and of the acid, but of the good iron which is taken away. It is difficult to predict in what direction the possibility of improvement lies; it may be in the discovery of some cheap solvent for the scale itself, in some electrolytic or other method of reducing the iron oxide, or perhaps in some mechanical or physical method.

Even though the remedy is not in sight the problem is of sufficient magnitude to warrant extended investigation.

Chemical Engineering Laboratory,
University of Wisconsin.

The Pittsburgh Testing Laboratory of Pittsburgh, Pa., announces that Mr. James Otis Handy, for 23 years chief chemist, has been appointed director of research and chemical engineering and that Mr. Howard H. Craver, for 14 years assistant chief chemist, has been appointed chief chemist of their laboratories.

The Old Freibergers in America held a pleasant dinner meeting on December 20th in the Hofbrau Haus, Broadway and Thirtieth Street, New York City. All old students of the Freiberg Bergakademie, who have not yet received notices concerning such meetings are requested to send their address to Mr. C. L. Bryden, 1015 Myrtle Street, Scranton, Pa.

A Curious Manifestation of Electric Constriction.

By Edwin F. Northrup, Ph. D.

If a trough of mercury having the dimensions shown in Fig. 1 be provided, and if a piece of copper sheet of the shape shown in Fig. 2 be floated upon the surface of the mercury, then, when twelve volts from a large storage battery are applied to the ends of the mercury in the trough, the following phenomena are manifested: The copper pieces when placed at either end of the trough with its rounded end pointing toward the far end will move with a speed of about 80 centimeters

FIG. 1.—DIMENSIONS OF TROUGH.

per second the length of the trough. If the copper piece is held stationary the mercury will be greatly agitated at its pointed end.

These effects are to be thus explained: Copper has about sixty times the conductivity of mercury. The current stream lines are thus very much more dense at the pointed end of the copper piece than they are at the rounded end. The elementary mercury filaments by their mutual attraction produce a greater pressure at the pointed end than at the rounded end, hence the copper "boat" moves rapidly forward.

The writer is not unaware that practical uses may be made of this manifestation of the pressure forces in a liquid carrying a current (direct or alternating). He has designed, on paper, what appears to be an excellent ammeter, and other uses are thinkable. If in a tube containing molten metal there is fastened a piece of solid metal of high conductivity and having the shape of a plumb bob, then when current passes the fluid metal would move rapidly if the solid piece cannot move.

Very much has been written about the "pinch" phenomenon, but the writer wishes to call attention here to the fact that it was he who first thoroughly investigated this phenomenon experimentally and deduced the equations which express all the laws of the phenomenon for a conductor of circular cross-section. These experiments and laws are fully set forth in an article by the writer entitled "Some Newly Observed Man-

FIG. 2.—DETAILS.

ifestations of the Forces in the Interior of an Electric Conductor," *Physical Review*, Vol. XXIV, No. 6, June, 1907, pages 474-497.

In a paper by the writer entitled "A New Type of Ammeter for the Accurate Measurement of Alternating Currents Above 1000 Amperes," presented at the meeting of the American Electrochemical Society, May 17, 1909, the writer showed how the forces in question had been applied by him to the construction of an accurate type of ammeter for measuring large direct or alternating currents.

Palmer Physical Laboratory, Princeton, N. J.

The Western Metallurgical Field.

Eastern and Western Spelter Conditions.

The situation with regard to the mining of zinc ores and production of spelter has not greatly changed during the past year. The high price of spelter naturally has spurred the miner to greater activity. There has been an increase in ore tonnage both East and West, but not along the same lines. The Joplin increase is shown in the marketing of 7000 to 8000 tons of concentrates weekly where the 1911 output was but 5000 tons. The ore is being extracted as rapidly as possible and rushed to market.

The Western increase is not so much in larger weekly shipments but in very substantial additions to ore reserves awaiting extraction. This reflects quite clearly the difference in operating conditions between East and West. Joplin mine and mill equipment is comparatively cheap, and the machinery is readily salable at second hand. Under these conditions ore reserves are not essential. Furthermore, the product is high-grade and meets a sure and immediate market. The Western operator requires a more expensive equipment, usually unsalable when worn, and finds a much more irregular and restricted market for his lower-grade output. Therefore, ore must be in reserve before he may safely provide proper equipment. It is quite likely, however, that actual shipments from the West during the latter part of 1912 would have been larger but for shortage of cars.

It has become more certain during the year that a considerable portion of the Western zinc tonnage will come from scattered ore bodies of moderate size rather than from large deposits, and these smaller ore bodies are quite uniformly complex and difficult to treat. No large bodies of high-grade ore exist in America to compare with Broken Hill in Australia, say, where 5,000,000 tons of tailings still await treatment and where there are still millions of tons of unbroken ore in the mines.

The only deposit approaching this is that of the Butte and Superior Mine in Montana, where about 3,000,000 tons of 20 per cent zinc is said to be fairly in sight. There is a tendency among some mining men to assume that methods adopted by the owners of this property may be blindly followed by most others having complex ores awaiting treatment. This may easily prove dangerous ground to take.

The Butte and Superior ore is notably free from iron and copper, as complex ores go, so that concentration and flotation yield high-grade zinc concentrates not requiring separation. Even the adjoining mines in Butte so far as now opened do not show the same clean ore.

Cost of Milling at the Liberty Bell.

At the mill of the Liberty Bell Gold Mining Company, Telluride, Colo., recovery of gold and silver is made by amalgamation, concentration and cyanidation. Situated in a district noted for high freight rates, wages and cost of living, the cost of treating a low-grade ore by this process is remarkably low, and specially interesting to engineers having similar obstacles to overcome. The figures given in the right-hand column represent operating conditions in October, November and December, 1911, and are based on the treatment of 104,460 tons of ore.

Kick's Law and Rock-Crushing Efficiency.

The use of Kick's law in computing the crushing efficiency of different machines has evoked considerable discussion, particularly on the Rand, where Mr. H. Stadler has been an advocate of this method. Recently some interesting work has been done at McGill University, in which Rittinger's law has been disproved and Kick's law adopted as more nearly in accord with the truth. The following extract is from a report issued by the University:

ROCK CRUSHING.—"A series of investigations have been carried on by a succession of fellows during several years on rock crushing, and the consumption of power has been very accurately measured for several standard types of crusher, work-

ing on different kinds of rock and crushing to different degrees of fineness. The result of these experiments is to finally disprove the 'law' of crushing originally enunciated by Rittinger

and accepted by nearly all authorities since his day, and to show that the more recent theory advanced by Kick is either true or so nearly so that it affords a close working approximation to the truth.

"Kick's 'law' was originally stated in 1885 as a general proposition in mechanics, and it is only within the last few years that it has been applied to ore dressing first by Stadler in South Africa, and more recently by the McGill staff. But in terms of rock crushing it may be stated as follows: The power necessary to crush a given quantity of any given rock from any known size to any other known size, will be directly proportional to the reduction in volume of the particles—in other words have a ton of rock all in pieces, say, 1 in. in diameter, it will take almost three times as much power to crush them to pieces $\frac{1}{2}$ in. in diameter as to pieces $\frac{3}{4}$ in. in diameter; or it will take twice as much power to crush from 1 in. to $\frac{1}{4}$ in. as from 1 in. to $\frac{1}{2}$ in.

"The law as above stated is of course impractical, first, because it makes no allowance for the imperfections of the crushing machinery, or for the difference between one kind of crusher and another, and second, because it is not a practical possibility to feed a crusher with rock all broken to exactly the same size; but as Stadler has pointed out, if the law is theoretically true, it is possible to take any quantity of mixed rock, and by sizing it before crushing and weighing the different sizes, then crushing, say, half the lot in one machine and the remainder in another, and finally by again sizing and weighing

the products, it is possible to determine the relative useful work done by each machine, or in other words to determine the comparative efficiencies of different crushers.

"The McGill experiments were first directed to settling the question of the truth of the theory and, as stated above, the results of a very large series of experiments agree with the law to within the reasonable limits of error of experiment on so variable a material as broken rock.

"The next thing to be done was to compare the efficiency of a single crusher, say, a Gates breaker, over different parts of its range, i.e., to determine whether it gave as high an efficiency when working from say, 4 in. to 1 in. as from 4 in. to 2 in. or from 2 in. to 1 in.; and similarly to study other crushers such as stamps, rolls, tube mills, etc., with a view to finding the most efficient range of each machine and the comparative efficiencies of the different machines.

"Obviously the amount of ground to be covered is enormous, especially as the experiments have to be carried out on a large scale yet with the utmost care to eliminate errors. Therefore, only a small part of the work has as yet been completed, but enough has been done to justify the preparation of a preliminary report which is now being prepared for publication, and it is confidently believed that it will soon be possible to state with a very considerable degree of certainty just what types of crusher are most suitable for particular degrees of crushing, and to state what output may be expected for any rock for which the confines have been determined."

Utah.

At a recent meeting of the Utah Society of Engineers, at Salt Lake City, Mr. H. D. Randall, of the General Electric Company, read a paper on the Hydro-electric Power Resources Tributary to Salt Lake City. He gave a list of the developed water-power plants, excluding a few of the smaller municipal systems, showing a total rated development of 66,850 kw. Of this quantity, Mr. Randall estimated that about 45,000 kw. is available for delivery in the tributary markets. As to the future possibilities, he estimated that 105,750 additional kilowatts could be developed, of which about 90,000 kw. would be always available.

The year 1912 closed without the discovery of any important new mining districts in Utah. Increased activity was noted, however, in all the old districts, with some progress in metallurgical work on ores from old or abandoned mines. The Mines Operating Company, which acquired the old Ontario at Park City last year, is reported to have completed its experimental work on the old low-grade ore, and has adopted a chlorination process. Cyanidation was first tried, and it was thought that the process would be successful, but further work indicated that it would not be best adapted to the general run of ore, and further experiments resulted in the decision to use a chloridizing roast, followed by leaching. Details of the process have not been made public, and probably will not be until the new mill is working satisfactorily.

The Utah Copper Company is again operating at full capacity, following the labor strike of last fall. On December 1, general manager Jackling issued a statement to the effect that the company was then mining 20,000 tons per day, and that substantially a full crew of men was at work. He also announced an increase of pay for pit men, track men and laborers of all classes, as well as for employees in the mechanical department. This applies to men working at Bingham, and is consistent with the increase announced a month earlier for men at the Garfield concentrating mills. The increase ranges from 20 to 25 cents per day, and will be effective during the period of relatively favorable prices in the copper market.

Dry Concentration in Colorado.

Events of recent occurrence indicate that dry concentration is to receive an impetus in Colorado, due to the activity of the Sutton, Steele and Steele Manufacturing, Milling & Mining Company. The company succeeds Sutton, Steele & Steele, Inc., of Dallas, Texas. A 50-ton custom and demonstrating mill is being built in Denver, where a tract of three acres has been

bought in the south part of the city. It will be ready for operation early this year, and will be the principal testing station of the company. In addition to this mill, the company will operate also the old Yak mill of the American Zinc Extraction Company, at the mouth of the Yak tunnel in Leadville. This mill has been closed for over a year, but has been purchased by the Sutton company, and will be in operation early this year, treating low-grade zinc sulphide ores of the Leadville district. Dry table concentration will be the system used at both these mills.

Company Reports.

The twelfth annual report of the *Consolidated Mercur Gold Mines Company*, Utah, has just been issued, covering the year ended June 30, 1912. In the eleventh report it was shown that the company's operations were on a precarious basis, with a prospect of a complete cessation of work. The present report does not hold out much hope for better conditions, although during the past year some new ore was found which has enabled the company to continue. The total quantity of ore milled was 201,652 tons, consisting of base ore (34 per cent), oxidized ore (59 per cent) and tailing (7 per cent) and yielding a recovery of \$2.45 per ton. The mill tailing had an average value of \$0.82. The total cost of milling is given as \$1.10 per ton. Cyanide consumption was 0.73 lb. per ton of ore; lime consumption was 15.27 lb.; zinc consumption, 0.5 lb.

Synopsis of Chemical and Metallurgical Literature.

Gold and Silver.

Metallurgical Costs at the Homestake.—From an exhaustive treatise on the metallurgy of the Homestake ore, published by ALLAN J. CLARK and W. J. SHARWOOD, in *Bulletin No. 98*, Inst. Min. & Met., we take the following summary of costs and metallurgical practice:

BREAKING ORE AT SHAFTS.		COST PER TON.		Approximate Per-centage of Total Cost of Break-ing.
		Range.	Average.	
		Cents	\$	
Power:	Steam power, including labor of engi-neers, firemen, etc.	3-4	0.0351	58.5
Attendance:	Labor, including the handling of cars from shaft to grizzly	1-1.5	0.0125	21.0
	Lubricants	0.08-0.14	0.0009	1.5
Maintenance:	Materials and supplies for repairs and renewals	0.65-1.2	0.0091	15.0
	Labor on repairs and renewals	0.14-0.38	0.0024	4.0
Total		5.7-6.6	0.0600	100.0

The cost of distribution of the broken ore to the mills by means of the tramway is approximately 2 cents per ton.

The following costs do not include amortization charges nor water supply; they do, however, cover superintendence, ordinary repairs and renewals, and a proportion of extraordinary renewal charges when the life of an installation may be estimated, as, for instance, the tube-mill lining and the pipe-lines conveying sand and slime.

The cost of Stamp-milling, at the lead mills of the company, for a period of twelve months, is as follows:

	Per ton crushed.
Power (including engineer's labor)	\$0.104
Machinery (renewals)	0.094
Operating labor	0.091
Silver plating	0.005
Mercury	0.005
Repairs (reconstruction of batteries, bins, etc.)	0.041
Miscellaneous	0.006
	\$0.346

At the North Side mills the cost is about \$0.27, the difference being almost entirely due to the electric drive at those mills.

Regrinding.—Costs for three-month period, 1910:

Per ton ground.	
Power	\$0.0634
Labor	0.0808
Renewals	0.1064
Miscellaneous	0.0064
	\$0.2570

METALLURGICAL SUMMARY.

A summary of the metallurgical operations, showing the amounts recovered at the various stages of the treatment, concludes our description. This covers the entire metallurgical system for a period of four months, when the ore was rather below the average in value. The North Side mills, where 36 per cent of the stamps are located, are often supplied with surface ores which are cheaply mined through glory-holes and open-cuts, so that ore of a total gold content of less than \$1.50 per ton may be treated at a profit. During the period covered by our summary the ore crushed at these mills aver-

	20.994	0.754	5.916	\$0.212
SLIME NOT TREATED			0.357	0.013
Totals.....	93.727	\$3.366	6.273	\$0.225

Total Value of Ore Crushed, per Ton, \$3.591.

This Table is very approximately correct. Slight errors exist in the stamp-mill distribution, as the variations in the silver contents of the various amalgams have not been considered, the distribution of the total amalgam value being based on the gold content only. The actual value of the amalgam from the lower rows of plates is therefore a trifle higher than here stated, and the battery correspondingly lower.

Lime-Burning.—Cost of a ton of lime (CaO), delivered on board cars at kiln, twelve-month period:

Stripping and Quarrying—Labor.....	\$1.03
Supplies.....	0.04
	\$1.07
Burning and Loading—Labor.....	\$1.13

Supplies, Repairs.....	0.11
	3.89
	\$4.90

aged \$2 gold per ton, while the average for the entire system was \$3.50. About 2 per cent of the ore crushed was wasted in the form of slime.

Pan renewals, per ton, ground in pans..... \$0.125

Tube renewals, per ton ground in tube-mill..... 0.036

Action of Calcium Sulphate on Cyanide Solutions.—In the *Journal of the Chem. Met. & Min. Soc. of S. Africa* for August, 1912, Joux Watson contributes some data on the effect of calcium sulphate on cyanide solutions, being a discussion of an original paper in the April, 1912, issue of the same journal, by ANDREW F. CROSSE. Mr Watson made some

experiments to ascertain the extent to which calcium sulphate decomposes a solution of potassium cyanide. Mill solutions used for sand and slime treatment respectively, were divided into separate portions and placed in bottles containing one litre each. To one portion of each kind of solution he added 2.5 g. of pure dried calcium sulphate and agitated well. The bottles were allowed to stand unstopped in the laboratory, and were shaken each day. The following table gives the results of tests made on treated and untreated samples of solution.

Time of Analysis.	UNTREATED SAND SOLUTION		TREATED SAND SOLUTION.	
	Free KCN	Alkalinity CaO.	Free KCN.	Alkalinity CaO.
As taken from sump	0.223%	0.059%	0.223%	0.059%
Three and one-half hours after addition of CaSO ₄ ...			0.214	0.059
After 2 days	0.214		0.202	0.059
After 4 days	0.192		0.184	
After 12 days	0.183	0.053	0.164	0.048
Percentage loss of KCN and CaO.....	17.93	10.2	26.45	18.6

A similar table shows results obtained on the solution used for slime treatment, in which the percentage loss of KCN and CaO were 46.8 and 52.8 for the untreated, and 59.3 and 87.6 for the treated solution. It must be remembered that the untreated solutions contained some calcium sulphate.

In a solution of sodium cyanide prepared with distilled water, and having the approximate strength of the sand solution used before, Mr. Watson added 1 g. lime to 2700 c.c. and divided the solution in three parts and allowed to stand for one day. Then to one part he added 2.07 g. CaSO₄, to another 29.7 g. Epsom salt, leaving the third portion untreated except with the previously added lime. Tests were then made on the consumption of KCN and CaO as before, with the result that after seven days the following percentage losses of KCN and CaO were noted: In the untreated solution, 0.4 and nil; in the CaSO₄ solution, 4.1 and 5.1; and in the Epsom salt solution, 22.3 and 26.4.

Cyanide Practice at Komata Reefs Mill, New Zealand.—In the *Mexican Mining Journal* for November, 1912, S. D. McMIKEN describes the changes made in the treatment of the Komata Reefs ore. Originally the ore was dry-crushed in stamps and cyanided. This failed to recover much coarse gold, so wet-crushing and amalgamation were adopted preceding cyanide treatment. Still later the process has been altered to include fine-grinding and slime treatment.

The ore, which is a hard, cherty quartz mixed with calcite and containing little sulphide, is crushed to 1½-in. size and fed to twenty stamps. The mortars are fitted with screens having 4½ holes per linear inch. Stamp capacity is 5 tons per stamp per 24 hours. The stamp product is roughly classified in pointed boxes, the underflow being fed to tube-mills at a consistency of 1:1. The tubes are 16 ft. by 4 ft., lined with Brown patent liners which last twenty-two months, grinding 38,500 tons of ore. The consumption of iron is 0.48 lb. per ton of ore, and of pebbles 2.2 lb. per ton of ore. Power required for two mills is 50 hp, the tubes running at 28 r.p.m. The following table shows the work done by the mills.

	On 20 Mesh %	On 25 Mesh %	On 30 Mesh %	On 200 Mesh %	Through 200 Mesh %
Tube-mill (16 ft. x 4 ft.)	25.5	25.2	16.5	14.8	18.0
Tube-mill charge		1.0	22.0	25.9	51.1

The finely-ground pulp is amalgamated on Muntz metal plates. This metal has been found superior to copper, being more easily kept clean, and absorbing less gold. Forty per cent of the gross value of the ore is saved by amalgamation.

After amalgamation the pulp is separated into sand and slime, which receive separate treatment.

The sand contains 40 per cent of material which will pass 200 mesh. Percolation is carried on in steel vats with filter bottoms of jute sacking. The sand is drained to 15 per cent moisture and treated with a wash of 0.05 per cent KCN solution. After percolation this wash is precipitated and run to waste. It serves the purpose of reducing the consumption of cyanide when the strong solution is put on, as it contains considerable lime. A strong solution of 0.8 per cent KCN is then run on and circulated through the sand for eight days before precipitation. It is aerated and treated also with ozone which is found to increase its activity. The strong solution is followed by one of 0.08 per cent KCN and then by water. The usual time of washing is fourteen days. Extraction is 93 per cent of the value of the sand.

The slime is thickened in Dorr thickeners, being first treated with lime at the rate of 20 lb. per ton. The Dorr discharge contains 40 per cent moisture. It is pumped to the Brown (Pachuca) agitators which are 38 ft. high and 10 ft. diameter. Power required for ten agitators is 8 hp, the air being compressed to 22 lb. per square inch. These tanks have been tried with short air-lift pipes, but they did not prove satisfactory on account of the tendency of the coarse slime to separate from the fine. The slime in the agitators is diluted with 0.1 per cent KCN solution until it contains about 65 per cent moisture. A common charge is 40 tons dry slime. Air agitation continues for five or six days, after which time the pulp is again thickened to about 45 per cent moisture. The overflow from this thickening is filtered through sand and precipitated. The thickened slime is filtered in a Moore filter of the "turnover" type invented by Mr. McMIKEN. A vacuum pump giving a vacuum of 24 in. mercury builds a cake 1¼ in. thick in 30 minutes. A wash of barren solution is given for about the same length of time required to build the cake. No water wash is given. The cake is discharged with 25 per cent moisture, with a loss of soluble gold amounting to 12 cents per ton, and of silver 4 cents per ton. The total extraction is 95.6 per cent of the value of the slime.

Precipitation is by zinc dust. The precipitate is given a sulphuric acid treatment (10 parts water to 1 of acid), after which it is dried and mixed with powdered borax glass in the proportion of five parts precipitate to one of borax. Melting is done in plumbago crucibles. The bullion is 900 fine, the ratio of gold to silver being 1:8. Amalgam from the plates yields bullion 990 fine, containing gold 600 and silver 300.

The total extraction from this ore is 96.4 per cent. This high extraction is assigned mainly to having large cyanide capacity per stamp.

Gitsham Cyanide Process.—The *Kalgoorlie Miner* gives some details of this modified cyanide process, in which ordinary potassium cyanide solution is acidified with sulphuric acid, giving rise to hydrocyanic acid. The solution is allowed to percolate through the ore in the usual way, but before precipitation it is neutralized with lime water. After precipitation it is again acidified and used as an extractor. The inventor claims that antimonial and copper ores can be worked without trouble, and that refractory ores generally yield their precious metals to this solution.

Photolyse.—Under this caption GASTON JACQUIER describes in the *South African Mining Journal* for Sept. 14, 1912, a process of precipitating cyanide solutions, in which photochemical effects play a part. Wooden tanks are provided with removable aluminium linings, and aluminium sheets are adapted to be suspended in the tank. The latter are arranged at right angles to the direction of the magnetic needle, and must be exposed to the sunlight. After twenty-four hours exposure all the gold and silver contained in the solution is precipitated on the aluminium sheets which are then removed and brushed to collect the precipitate. The aluminium does not in any way change or lose weight. The reader will recall in this connection the "luminator" purification of water, mentioned in our issue for November, 1912, page 762, in which

aluminium is used in direct sunlight for the treatment of water for boilers. Here also a photochemical effect is suggested, as the aluminium does not change nor lose weight.

Estimation of Lead in Cyanide Solution.—In the *Mexican Mining Journal* for December, 1912, J. E. CLENNELL gives methods for determining lead in cyanide solutions. For rapid approximate determinations the author proceeds as follows:

The solution is filtered if necessary, and 100 c.c. is agitated with an excess of sodium carbonate or bicarbonate, usually 0.3 to 0.4 g. is sufficient. The precipitate which consists almost exclusively of lead and calcium carbonates, without copper, gold or silver, is allowed to settle, and is then washed on a filter until free from cyanide. The residue is then dissolved in hot 20 per cent acetic acid, and the liquid transferred to a measuring flask of from 100 c.c. to 500 c.c. capacity. A measured volume of standard potassium bichromate solution is then added, more than sufficient to precipitate the lead, and the flask filled to the mark with distilled water. After thorough agitation the precipitate is allowed to settle, and an aliquot part of the solution drawn off in a pipette. Filter if necessary. The excess of bichromate is titrated with a ferrous sulphate solution of corresponding strength, first adding a few drops of hydrochloric acid. Potassium ferricyanide is used as an indicator as in the bichromate titration for iron. The bichromate and ferrous sulphate solutions should be standardized against a lead solution of known strength. A convenient standard is one containing 1 g. lead per litre. One gram of pure lead foil is dissolved in the least possible quantity of dilute nitric acid, sodium carbonate is added until a permanent precipitate is formed, and then acetic acid until everything is in solution. The solution is made up to one litre with distilled water.

An alternative method is as follows: 100 c.c. cyanide solution is heated to boiling and a slight excess of sodium sulphide added. One or two cubic centimeters of a 10 per cent solution is sufficient. The precipitate contains sulphides of lead, silver, zinc and possibly mercury. Wash by decantation and finally on the filter until the residue is free from soluble sulphides. Wash the precipitate off the filter and cleanse the latter with 10 c.c. of boiling 50 per cent nitric acid, allowing the liquid to run into the vessel containing the precipitate. Concentrate to small bulk, cool, remove globules of sulphur, add to c.c. sulphuric acid and evaporate to white fumes. Cool, add 50 c.c. water and boil; cool and allow to settle, using 10 or 20 c.c. alcohol if the precipitate is small. Filter and wash with 5 per cent sulphuric acid. The filtrate contains the zinc and silver. Dissolve the lead sulphate in sodium or ammonium acetate, transfer to a measuring flask and add bichromate solution as in the preceding method and finish as there indicated.

Flotation of Minerals.

"Agitation Froth" Process.—In our last issue we published an abstract of an article by J. W. ASHCROFT, taken from *Bulletin* No. 97, Inst. Min. & Met., describing the operation of the flotation process on a copper ore in New South Wales. In *Bulletin* No. 98 of the same society, Mr. H. L. SULMAN gives a discussion of Mr. Ashcroft's paper, in which some essential details of the minerals separation process are given. Mr. Sulman suggested that the term "froth flotation" or "agitation froth" process be applied to the method under discussion, since an essential factor in successful treatment was the obtaining of a thick, substantial or "matted" froth, necessary to support the coarser mineral particles. If the floating mass becomes thin or skin-like, it does not afford the same opportunity to recover coarse mineral. If necessary, the area of the flotation chamber has to be constricted to produce a thick froth.

By mere vigorous agitation of ore and water and the addition of a minute proportion of oil, say 2/3 lb. crude eucalyptus oil per ton of dry ore (as in the case under discussion), froths were produced which carried over 80 per cent of the total mineral as a concentrate assaying over 20 per cent copper.

This was obtained from an ore assaying only 3½ per cent copper. From poorer ores the flotation process was obtaining elsewhere 90 per cent of the mineral as a concentrate containing 22 per cent or 23 per cent of the metal.

While the process is by no means a delicate one and requires no intricate adjustments or highly skilled supervision, certain conditions are demanded, as follows:

The ore sent to the flotation department should be of uniform consistency, say four or five parts water to one of ore.

The feed should be uniform as to rate of flow and mineral content. If either factor is subject to wide variation, plant adjustment would be required accordingly.

The mesh to which the ore is crushed should be that at which the best results can be obtained, and should be determined for each ore.

The power applied to the agitation spindles should be uniform; the agitation should not be alternately rapid and slow.

Failure to apply these conditions will give poor results which cannot properly be charged to the process.

The "froth flotation" process is now being applied to a wide variety of ores; zinc-lead, copper, silver, molybdenum and others. At the Braden mine, South America, a plant is installed to treat 3600 tons per day of low-grade chalcocypite.

The power required for agitation is about ¼ hp to ¼ hp per box; thus an eight-box unit would require about 6 hp. The agitation shafts revolve at about 300 to 350 r.p.m., the peripheral speed of the impellers being some 1500 ft. per minute. The cost of a flotation plant of this type is far less than for a wet concentration unit of similar capacity.

Mr. WALTER BROADBRIDGE contributed the following data regarding the flotation methods at the Braden Copper Co., in Chile. A change was made at this property, substituting the minerals separation process for wet concentration of low-grade copper ore. At present a 3000-ton flotation plant is under construction. The copper minerals are chalcocypite, bornite, chalcocite, cuprite, metallic copper and the carbonate and silicates of copper. The recovery by wet concentration is given as 50 per cent to 60 per cent. In a test run by flotation the averages were as follows: Ore, 2.61 per cent copper; tailing, 0.56 per cent; concentrate, 21.19 per cent; recovery, 80 per cent. Consumption of chemicals was 3.57 lb. H₂SO₄ and 2.33 lb. Texas and wood tar oils, per ton of ore treated. The estimated cost was 10d. (80.20) per ton, based on a treatment of 1,000,000 tons per annum.

Combustion.

Surface Combustion.—In *Feuerungstechnik* of November 15, 1912, Dr. C. KINZBRUNNER reviews the different theories which have been proposed by Schnabel, Bone, Ellis, Leather and Lucke concerning the mechanism of "surface" or "flameless combustion" and reaches the conclusion that its essential feature is the combustion of large quantities of gas and air in approximately theoretical proportion concentrated into a small space, while the use of porous refractory materials permits an automatic regulation of the combustion zone within the pores of the mass and the incandescent surfaces exert a strong catalytic effect. The combustion is not flameless, but as the place of the flame is within the incandescent porous mass, it is not visible to the outside. "With respect to its practical applications the invention may become of about the same importance for the technics of firing as the invention of the incandescent gas mantle has become for lighting."

Recent Chemical and Metallurgical Patents.

Iron and Steel.

A method of treating metal ingots to prevent piping and segregation has been patented by GROVE H. BENJAMIN, of New York City. As a preliminary step in the production of the ingot, the molten metal is poured into a mold which is so constructed that one of its sides shall have a higher temperature than the other three sides. This may be accomplished by heating one side of the mold or by providing cooling means for the other sides. By casting the ingot in such a mold one of its

sides will retain a higher temperature than the others and the soft metal on the hotter side will accommodate the shrinkage on the cooler sides and prevent the formation of pipes. When the ingot is cool enough to handle it is removed from the mold and placed in a machine between pressure plates mounted on shafts and carried in suitable bearings. One of the plates has an adjustable part that can be used to compress a part of the soft side of the ingot while cooling takes place. Also, during the exertion of this pressure, the ingot can be rotated to overcome the tendency toward segregation of the materials forming the ingot. (1,038,271, Sept. 10, 1912.)

Gun Barrel and Similar Steel.—**Franz Hatlanek**, of Kladno, Austria, endeavors to improve the wearing qualities of steels which are subject to repeated alternating heating and cooling, such as the barrels of guns and cannons. The continual expansion and contraction of such steel causes a destruction or a change in the texture of the material which weakens it. The metal is then less capable of enduring any other additional strains. An addition of from 4 per cent to 5 per cent copper is said to perform this improvement. It has the further advantage of making the steel more indifferent against the action of residues of the combustion of explosives. The pits and spots of rust which form in an insufficiently cleaned weapon impair its shooting accuracy considerably. It has been found that a steel with 7 per cent Ni and 4 per cent Cu did practically not rust in a moist atmosphere of nitric acid, nitric anhydride and carbonic acid. The resistance to rusting becomes specially evident when the percentage of nickel in a gun steel is made slightly higher than the usual 3 per cent. (1,005,115, Oct. 3, 1911.)

Flue Dust.

Dust Separators.—Devices for separating dust and solid particles from blast-furnace gases by subjecting them to centrifugal action have been patented by several inventors. Recently **JULIUS A. DYBLIE**, of Joliet, Ill., has proposed the device shown in vertical and horizontal sections in Fig. 1. The vertical section is on line 1-1 of the horizontal, and the latter on line 2-2 of the former.

The catcher consists of a casing 10 mounted on a base 11. The dust-laden gas enters at 18 and passes through the spiral passage 21.

The dust is forced to the outer edge of the spiral and falls through its open lower edges into the dust-collecting chamber 12, and thence to the outlet 14, where it is held by the cap 15 until removed. A certain portion of the dust is caught also by the hook 25, and drops downward into the collecting chamber.

The clean gas passes through the aperture 24 into the central chamber 22 and thence upward into the portion 30 of the dust-catcher to the outlet pipe 31. Any dust which passes into the central chamber 22 can pass downward by gravity to the chamber 12. (1,045,532, Nov. 26, 1912.)

In Fig. 2 is shown the device of **LAWRENCE ANDERSON**, of Chicago, Ill., in its relation to a blast furnace. The separator consists of a metal pipe C^1 having the form of a helical coil C^2 . The force of the blast from the furnace drives the dust-laden gas through the coil, throwing the solid particles to the outer surface thereof. Here they are arrested in the pockets d^1 from which lead pipes d^2 ending in extensions d^3 , which dip into water, thus sealing the pipes against the exit of gas. The coil shown is divided into three parts of four convolutions each. In the first a dry separation takes place; in the second a water spray is introduced by the water pipe C^3 and its extensions. In the third section the cleaned and washed gas is dried by centrifugal action, and finally delivered to a tank connected with the outlet C^4 . (1,039,008, Sept. 17, 1912.)

Treatment of Flue-Dust.—**JOHN I. SOUTHER**, of Westmont, Pa., has patented a method of treating flue-dust by agglomerating or sintering it into a rough lumpy condition by means of high heat applied to the dust in a revolving cylindrical furnace, using blast-furnace gas as a fuel. (1,041,363, Oct. 15, 1912.)

Zinc, Copper and Nickel.

Zinc Digester and Filter.—One of the patented features of the zinc reduction process of **PERCY C. C. ISHERWOOD**, of Leytonstone, England, is a digester and filter illustrated in Fig. 3. The patent is assigned to the Refractory Zinc Ore Treatment Company, a corporation of New York. The object

FIG. 1.—DUST COLLECTOR.

of this invention is to provide means for filtering a solution of zinc while hot, so that the zinc salt cannot crystallize out of the solution. The digester consists of a vessel a mounted on trunnions and adapted to be inverted. The cover b has a valve d , and when in place holds a filter c at the point shown. A mixer e is used to stir the charge of zinc-bearing material during the process of solution. Heat may be applied in any manner, as by a gas burner f . When solution is complete the digester is in-

FIG. 2.—DUST SEPARATOR.

verted, whereupon the mass within falls on the filtering medium and the zinc liquor passes through due to the pressure inside the tank. The operation is similar in some respects to that of a chlorination barrel, but is only one step in a process which involves solution of zinc in sulphuric acid and ultimate electrolysis. (1,043,939, Nov. 12, 1912.)

Repairing Copper Converters.—An invention designed to facilitate the repair of converters has been patented by E. A. C. SMITH, of Baltimore, Md. Usually it has been necessary, in repairing a large converter, to remove it from service and allow it to cool sufficiently to permit a workman to enter it. Mr. Smith has patented a feature which will make the region of the tuyeres accessible without the usual trouble and expense. The arrangement is such that a portion of the casing may be removed so that the lining in the tuyere zone can be reached from without by the workman. The use of the invention permits the repair of tuyeres and lining within a few hours, whereas formerly several days were required for the same work. When it is desired to repair the lining at any point along the tuyere zone, or to remove a corroded or defective tuyere, the casing section nearest the point of repair is removed, thus leaving an aperture through which the repair can be made. On completing the work, the removable section is replaced and wedged in position. (1,044,587, Nov. 19, 1912.)

Hardening Copper.—The use of potash, ferrosilicon and limestone in different proportions and modified by the addition of other ingredients is the basis of a patent granted to JULIAN KICH, of Lyndora, Pa. As an example of a mixture which will give the desired result, the inventor uses the following: $\frac{1}{2}$ oz. each of ferrous sulphate, copper sulphate, ferrosilicon, potash, limestone, manganese, phosphorus, and welding compound. The last is composed of boric anhydride, 50 per cent; iron oxide, 15 per cent; soda, 15 per cent, and potash 20 per cent. The mixture first mentioned is added to molten copper in the proportion of 1:3. Modifications of the formula are claimed to give different results. (1,041,297, Oct. 15, 1912.)

Purifying Metals.—For the purification of copper and other metals, particularly for the removal of arsenic, AXEL G. SUNDBERG, of Helsingborg, Sweden, has patented the use of an alkali carbonate. In practice the inventor prefers to add the alkali carbonate, say sodium carbonate, to the bath of

per cent silicon. Such alloys have a limit of elasticity of 12.7 to 19 tons per square inch, tensile strength of 30.5 to 34.9 tons per square inch, extension of 25 to 35 per cent, and a high resistance to the notch bending test. They can be drawn, rolled and hammered at normal temperature, and can be wrought, rolled and pressed when hot. (1,040,027, Oct. 1, 1912.)

The economical manufacture of brass on a large scale is the basis of a patent granted to LAWRENCE ADICKS, of Chrome, N. J. He proposes to melt copper in a reverberatory furnace, such as is used for copper casting, having a capacity of from 20 to 250 tons per twenty-four hours. By means of a suitable ladle, several tons of copper is withdrawn from the furnace and the necessary quantity of zinc added and quickly incorporated. The 2 or 3 tons of brass is then promptly cast from the ladle into ingots. (1,041,940, Oct. 22, 1912.)

Alloy of Titanium and Copper.—ISADOR LATOFF, of Cleveland, Ohio, has patented a method of alloying or compounding titanium and copper without melting the same at the high temperature which would be required for the combination of the primary metals. He uses the oxides of the two metals, TiO_2 and CuO , and incorporates with them a suitable binder, such as oil. The mixture is then molded into any desired shape and introduced into a muffle furnace where it is subject to the action of a reducing atmosphere, such as carbon monoxide, at a temperature of from 600 deg. C. to 800 deg. C. To further insure the reducing atmosphere the molds may be packed in powdered coke. At the temperature mentioned the reduction proceeds, starting with the copper oxide and continuing catalytically with the titanium oxide. The reduction and combination is thus said to be effected at a temperature below the melting point of copper. (1,042,694, Oct. 29, 1912.)

Nickel.

Reduction of Copper-Nickel Ores.—According to patent specifications recently issued to WILHELM BORCHERS, of Aachen, Germany, and HARALD PEDERSEN, of Trondhjem, Norway, the following process may be successfully used in the treatment of copper-nickel ores:

First, the ore is smelted, preferably in the electric furnace, producing a crude matte containing practically all the nickel and copper originally contained in the ore.

Second, the crude matte is roasted in such a manner that both copper and nickel are for the most part converted into sulphates, while the iron forms oxide. This can be done at a temperature of 600 deg. C.

Third, the copper and nickel sulphates are dissolved with acidulated water obtained by passing the roaster gases in a counter stream of water in a percolation tower. This water will contain sulphurous and sulphuric acids.

Fourth, the residue from this leaching operation, consisting principally of iron oxide, but containing also undissolved copper and nickel, is resmelted to form new matte. As the iron oxide favors the oxidation of iron sulphide to oxide, and therefore into slag-forming material, it aids in the formation of a richer matte.

Fifth, by adding calcium or sodium sulphide to the solution obtained from the leaching process, copper is precipitated as a sulphide. After separating this by filtration more calcium or sodium sulphide is added for the precipitation of the nickel as sulphide.

Sixth, the sulphides thus separately obtained are reduced to their respective metals by smelting with suitable fluxes, say limestone and carbon. Calcium sulphide will be obtained as a slag.

Seventh, the calcium sulphide obtained from the sixth operation is converted into sodium sulphide, if desired, by treating with suitable sodium compounds, as sodium sulphate in aqueous solution. The sodium sulphide thus obtained is used as a precipitating agent, in the fifth step, thus giving sodium sulphate solution which may be reduced to sodium sulphide by more calcium sulphide.

None of the steps in the process is novel in itself, but in combination they form a useful and economical method, possessing several advantages over previously proposed methods. In

FIG. 3.—ZINC DIGESTER AND FILTER.

molten copper by introducing it in a current of air or gas beneath the surface of the metal. This procedure effectually removes arsenic which may be combined as arseniate of copper, forming sodium arsenate, which rises to the surface as a slag. Copper containing 0.02 per cent arsenic has thus been purified to an arsenic content of 0.002 per cent by blowing in sodium carbonate in quantity less than $\frac{1}{2}$ per cent of the copper. (1,043,371, Nov. 5, 1912.)

Alloys.—A brass possessing valuable qualities has been patented by ALFRED SCHMID, of Zürich, Switzerland. To an alloy of copper and zinc he adds, as an exclusive adjunct, silicon and tin. This produces a metal of high limit of elasticity, toughness, soundness, resistance to the attack of salt water, dilute acids and alkalis, and no undue resistance to cutting tools. The following example is given: 58 lb. copper is melted and superheated; to this is added, while stirring, 40 lb. zinc, 1 lb. tin, and 1 lb. silicon copper, the last containing 30

the smelting tests, slags were made containing less than 0.1 per cent copper and nickel. (1,043,291, Nov. 5, 1912.)

Another process for the same purpose has been patented by HORACE L. WELLS, of New Haven, Conn. He takes a matte of copper and nickel, produced by smelting their ores, and grinds it to a fineness of 60-mesh. The matte is then treated with dilute hydrochloric acid (18 to 25 per cent HCl) at a temperature between 110 deg. Fahr. and 212 deg. Fahr. Most of the nickel will be extracted at the first application of acid, but a second is necessary to complete the extraction. The second acid solution thus obtained may be used on fresh matte. (1,044,316, Nov. 12, 1912.)

Aluminous Abrasive Material.

The production of a new abrasive is patented by AUGUST F. BLOVIN, of Springfield Township, Delaware County, Pa. An example of his material is given as follows: 100 lb. of an aluminium ore containing 78 per cent Al_2O_3 , 12 lb. anhydrous borax, 0.3 lb. chromite, and 4.75 lb. carbon. The mixture is fused in an electric arc furnace and the product crushed and cleaned for abrasive purposes.

Furnaces.

Improved Grondal Furnace.—An improvement in furnaces of the channel type has been patented by NILS V. HANSELL, of Bloomfield, N. J., and assigned to the American Grondal Company, a corporation of New York. In furnaces conforming to the Grondal patent it is customary to load the briquet trucks at some distance from the furnace and feed them to a preheating chamber which is aligned with and forms a continuation of the furnace proper. Where land is valuable this form of furnace requires too much ground, and it is the object of the present invention to provide a furnace requiring less space as to length. Furthermore, in the old type of furnace it is customary to mingle the air blown beneath the trucks to cool them, with the combustion gases after they have left the combustion chamber, and discharge them through a common stack. The combustion gases, however, contain valuable by-products which may be recovered and it is another object of the improved furnace to keep the cooling air and combustion gases separate and thus avoid diluting the latter.

In the new form of furnace the preheating chamber is located adjacent and parallel with the combustion chamber. The latter is graded upward from its entrance to discharge point, so that the newly loaded trucks may return by gravity through the preheating chamber. In the combustion chamber the gases of combustion and the cooling air are kept separate by the usual means of a sand seal on the sides of the furnace. In the entrance vestibule of the combustion chamber, however, it is necessary to provide some means of preventing the air and gas commingling as the truck is fed into the chamber. This is accomplished by means of a shield which follows each car into the chamber and maintains the gas above the trucks separate from the cooling blast beneath it. (1,043,695, Nov. 5, 1912.)

Acid-Proofing the Floors of Battery Rooms.

A great deal of attention is being given to the proper method of acid-proofing the floors of battery rooms. It is recognized that nothing can be done to make a concrete floor in itself acid proof. They have been treated with linseed oil thinned down with gasoline, but this method has retarded the action of the acid only temporarily. Acid-proofing preparations have been tried out by one of the leading concrete construction companies of New England but have not proved a uniform success.

The general construction of the floor of a battery room consists of vitrified brick or tile placed on a concrete base. Leading authorities state that the best way to acid-proof such a floor is to place several layers of acid-resisting felt cemented together with an acid-resisting compound between the brick and the concrete. The correct way to do this is first to give the concrete floor a coating of hot compound, then lay in this several thicknesses of felt lapped so that the joints of one

layer break joints with the under layer. Where this procedure is followed it is necessary to use sand for embedding the brick. To protect the walls and any columns in the battery room it is advisable to turn up the felt for a foot or so at the walls or columns, putting three courses of brick against the felt and pouring the compound behind the brick so as to make a tight joint.

The New York Edison Co., which is noted for using large factors of safety in all of its construction, takes extra precautions in acid-proofing floors. They usually specify two distinct courses of several layers of acid-resisting felt cemented together with acid-resisting compound.

In one of the recent specifications of this company for the floors of a transformer and battery station, it is stated that the contractor should spread over the rough concrete floor a layer of 1½-in. cement mortar finished with a smooth surface. As far as acid-proofing is concerned the specifications were as follows:

ACID-PROOF FLOOR CONSTRUCTION.

"Over the cement mortar surface shall be laid three layers of Hydrex felt bonded with Hydrex compound. The cement surface shall first be coated with a continuous and uniform layer of compound, to which it must adhere at every point. Where the felt is turned up on the walls and drain boxes an additional layer of felt and compound running parallel with the intersection of the two plane surfaces shall be applied.

"Over the completed acid-proof course shall be applied a layer of compound.

"Immediately after the acid-proofing is cool or soon enough after to insure against damage, the contractor shall spread a layer of cement mortar about 1½ in. thick over the entire horizontal area of the acid-proof course. This will form, after setting, a working surface on which the rest of the work shall be built."

After the protecting layer of cement mortar has set the specifications call for a course of concrete with a cement mortar finish and on top of this a second layer of acid-proofing consisting of two layers of the acid-resisting felt with three courses of the hot compound. Upon the top of this last acid-proofing course was laid bricks, the joints of which were filled with the hot compound as specified above.

It is interesting to note that the tests of the New York Edison Company have shown that the felt and compound used in this connection are not at all affected by sulphuric acid solutions.

An Improved Metallurgical Microscope.

By Wirt Tassin.

The value of metallographic methods in mill control has been recognized but the usefulness has been limited by the lack of portability in the appliances necessary for their use. This has made it difficult to study the forging, the casting or the bar as a whole, with the result that the metallographic field has to a large extent been limited to the examination of more or less small specimens cut from the piece and which may or may not be representative of the mass.

In June, 1910, I described in the *Iron Age* an illuminator which, attached to the metallographic microscope materially increased its compactness. I now propose to describe a com-

plete metallographic outfit which is light, compact, and portable and may be used either in the mill or in the laboratory and is equally serviceable for the study of the ingot, the forging, the bar, the casting or the small specimen, and which, it is believed, will meet the needs of the metallurgist, the engineer of tests, and the inspector.

The apparatus consists of a camera, microscope and illuminating device, all self-contained (Fig. 1).

The illuminating device consists of a tube which carries the lenses and is mounted in a sleeve provided with a set-screw to lock it in any position. Attached to this sleeve by means of a trunnion is a hanger. This is fastened by a set-screw to an arm which locks into the barrel of the microscope. The rear of the tube carries a shield which is provided with clips to hold the source of light when electricity is used and is slotted to hold a rod and lamp carrier when gas is used.

The source of light may be an acetylene jet or an electric lamp.

When acetylene is used the gas may be obtained from a generator or from a "Prestolite" tank. The lamp is a "Twentieth Century" jet, the support for which is held in a carrier made of two pieces of tubing brazed together at right angles. Each piece is provided with a set-screw so that the jet may be moved up or down, front or back, turned on its axis and set at any desired distance with reference to the plane of the lenses of the condensing train. The apparatus as arranged for illuminating with gas is shown in Fig. 2.

When electricity is used the lamp is carried in a socket fixed in an insulated metal hood. The whole is held in position with reference to the lenses of the condensing train by means of clips fastened to the shield. This arrangement provides for an up and down movement of the light. The apparatus as arranged for illuminating with electricity is shown in Fig. 1.

The current may be obtained from an accumulator or by cutting down the street supply. A convenient lamp bank to reduce street current for use with Mazda miniature lamps is wired as in Fig. 3. The lamp resistance needed with a 110-volt current is:

Two 32-cp and one 16-cp carbon lamps for a 6-volt, 16-cp Mazda miniature lamp.

One 32-cp and one 8-cp carbon lamp for an 8-cp Mazda miniature.

One 32-cp and one 4-cp carbon lamp for a 6-cp, 6-volt tungsten.

One 4-cp and one 16-cp carbon lamp for a 4-cp, 6-volt tungsten miniature lamp.

The lamp recommended is a 6-volt, 16-cp, headlight Mazda, No. 12 G., candelabra base.

The microscope consists of a barrel and draw tube mounted on a handle arm and provided with a coarse and fine adjustment, the latter of the lever type. Attached to the barrel just below the draw tube is a collar which holds a rod controlled by a set-screw. The base of this rod rests on the handle arm. The arrangement prevents the possibility of the coarse adjustment overhauling when the camera is in use. The base of the microscope is the stage. Through the center of this is a 1-in. circular opening which affords free space for the objective when examining large masses below the stage. Leveling screws are provided which permit of the adjustment of the apparatus perpendicular to nearly any surface. The advantages of this are to be seen in Fig. 1 where the microscope is shown mounted on a 6-in. shaft. Provision is made for the use of a detachable mechanical stage when needed.

The camera is attached to the barrel of the microscope by a tube which slips in and out like the draw tube and may be removed with the same ease. The whole moves with and becomes a part of the barrel so that any degree of focusing is possible. The distance between the eye piece and the ground glass is a constant, so that the amplification is a standard for all magnifications. The image is $3\frac{1}{4}$ in. in diameter and is formed on a $3\frac{1}{2} \times 3\frac{1}{2}$ -in. plate. The time required for the exposure is rarely over 10 seconds.

The apparatus packs in a space $12 \times 12 \times 5\frac{1}{2}$ in. A suit case

fitted with compartments to hold the various parts makes a very convenient container. One that measures 12 in. in width by 24 in. long by 6 in. deep, will hold the camera, the microscope and all its accessories, the lamp bank or an acetylene

FIG. 1.—MICROSCOPE CAMERA, ILLUMINATING DEVICE AND LAMP BANK, AS USED WITH ELECTRIC LIGHT AND MOUNTED ON A CINCH SHAFT

generator of the "Neverout" type, four plate holders, four boxes of plates, two tanks, one for developing and one for fixing, together with the chemicals necessary for etching and for developing. The suit case when fitted with a curtain also serves as a dark room.

In examining a large piece such as an engine frame the surface is "spot polished" in as many places as desired. A dam of modeling wax is then built around the spot to hold the etching medium and when the etching has been completed the dam is broken, the surface washed with water and gasoline and the

FIG. 2.—MICROSCOPE, CAMERA DETACHED WITH ACETYLENE LIGHT AND MECHANICAL STAGE

microscope adjusted and all is ready for the visual examination and the taking of a photographic record.

To polish, use is made of a portable 14-hp motor with a flexible shaft. As it is almost impossible to hold a wheel steady in the hand to give a surface flat enough for a microscopic examination use is made of a steady rest somewhat like the "Old man" of a drill. This insures a uniform bearing for the grinding wheel and with the proper gradation of the abrasive a mirror polish is obtained without much difficulty. A 130 F. car-

borundum wheel is used for surface grinding and is followed by a set of buffs charged with flour emery paste, washed flour emery paste and gold rouge in the order given.

Arrangements are under way for the manufacture of the apparatus and when completed it may be secured from the Arthur

FIG. 3.—WIRING OF LAMP BANK.

H. Thomas Company, of Philadelphia, who are already prepared to furnish the illuminating device which may be attached to any microscope.

Washington, D. C.

Application of the Moore Filter to Rapid Filtration and Purification of Sewage.

In our December issue we mentioned a very successful exhibition given on November 20 of a new sewage purification process at the laboratory of the Moore Filter Company and Chemical Process Company in New York City, at which rep-

FIG. 4.—MANGANESE SULFIDE AND SLAG X 150 IN A MAN-HOLE COVER—TAKEN WITH THE APPARATUS.

representatives of the water departments of various Eastern cities were present.

It is essentially an application of the well-known Moore vacuum filter to rapid sewage filtration. The chemical features of the process are the invention of Mr. James M. Neil. The rights to the patents are owned by The Chemical Process Company, 170 Broadway, New York City.

From a description of the process, given out by the company, we extract the following information. The system is called the M. S. D. & W. P. or Municipal Sewage Disposal and Water Purification System.

"The operation of the process requires the use of suction pumps, and vacuum filters whose surfaces are permeable to liquid and impermeable to solids. Movable vacuum filters are preferably used so that the separated solids can be removed from the sewage tanks at will.

"The flow of sewage to be treated is directed into a tank or other suitable receptacle, first passing it through a screen or screens in order to remove the floating and other large bodies

therefrom. In this tank suitable precipitants are added to the sewage (greatly in excess of the amount actually required for precipitation of the organic matters) and the whole intimately mixed by agitation, which may be effected by air, steam or water pressure, or by mechanical means, or by a combination of these forces. Such agitation and aeration are maintained continuously during the process, in order to break up and granulate the solids and to commingle the precipitable and fatty matters with the precipitant so as to render them in a condition amenable to collection on the filtering medium and to effect complete precipitation and final separation of the solids from the fluids in the manner hereinafter described.

"By employing an excess of precipitant in the treatment tank its effect is practically instantaneous while owing to the fact that no solids consisting of precipitant or solids in the sewage can escape through the filtering medium the consumption of precipitant is not greater than the amount actually required to effect complete precipitation of the organic and foreign matters contained in the mixture.

"The vacuum filter is placed in the treatment tank at a point preferably remote from the sewage inlet, and when it is submerged and suction begun a continuous flow of the agitated mixture is drawn toward the medium, on the surfaces of which the excess precipitant, precipitates and other solids in suspension in the mixture are deposited, while the liquid is drawn through the film or cake of precipitant and the filtering medium to the pump discharge.

"Complete precipitation and instantaneous separation of the purified fluid from the solids are thus effected.

"The operation may be continued until the deposit of solids becomes so thick on the filtering medium as to unduly interfere with the volume of liquid being drawn through it. This will be indicated by the vacuum gauge. The medium may then be raised from the sewage tank and moved to the dumping point, suction being maintained to hold the solids thereon during its removal, and in order to dry the solids, the medium may be held suspended in the air under suction as long as desired before dumping.

"When suction is stopped the cake of solids falls from the medium, or its removal from it may be assisted by a reverse current of air. After dumping the cake, the medium may be returned to the sewage tank, and the operation repeated indefinitely.

"Instead of raising and moving the medium every time it is loaded, the suction may be momentarily stopped and the solid matters thrown back into the mixture and again subjected to the forces of agitation in the tank—a reverse current of fluid or air may be used to assist in such throwing off.

"Suction being resumed again, the operation of loading is repeated, and when the surfaces of the medium are again sufficiently coated the solids may be again thrown back into the tank and these operations of loading and unloading may be repeated until it becomes desirable to remove some of the accumulated solids from the tank, which may be done in the manner already described.

"There being a continuous flow of sewage into the tank carrying valuable ingredients, this method of operation results in displacing the excess of precipitant from the cake with these ingredients. The cake may thus be finally recovered in a concentrated and highly desirable condition for subsequent treatment whereby the oils, greases, etc., may be liberated by any of the well-known methods and the residue used as a fertilizer.

"Several mediums may be used loading, drying and discharging alternately, so that the process may be carried on continuously. Extra tanks and mediums may be used when necessary to cope with a large or varying supply of sewage, the pump or pumps being always run at a capacity equivalent to the flow of sewage, and suitable precipitants added during the operation in sufficient quantities to deal with the amount and character of the sewage being treated.

"Heretofore in the art of treating sewage it has been found

necessary to use large quantities of hypochlorite or other germicides in order to destroy harmful bacteria. By this process harmful bacteria are almost entirely destroyed, so that in order to insure their complete destruction only a comparatively small amount of germicide need be used. This may be added to the mixture in agitation in the sewage tank, or it may be added to the effluent after it has been separated from the organic and solid matters.

"The results obtained by the above process and which have been effected without the use of a germicide are remarkable. Numerous tests of effluents obtained from samples of sewage originally rich in organic matter and harmful bacteria treated by the usual methods of precipitation and separation were found to be still high in organic matters, and dangerously high in harmful bacteria contents, while comparative tests of effluents obtained from the same sewage treated by this process showed them in every case to be entirely free from organic matters and harmful germs.

"Important features of the process are that it can be operated in open tanks without creating objectionable odors and at a minimum expense for labor."

At the exhibition of the process it was stated that the precipitant used in the process was simply waste material from paper mills, but that lime may be used instead.

PERSONAL.

Mr. William F. Carroll, formerly with the Compania Metalurgica Mexicana, at San Luis Potosi, has gone to Pachuca, Hidalgo, Mexico, for the Blaisdell Coscoticlan Syndicate.

Mr. A. F. Flynt, metallurgist, of Tepic, Mexico, has returned to the southern republic after an extended visit in the United States.

Mr. R. W. French, superintendent for the United States Refining & Reduction Company, at Florence, Colo., will spend the winter in Arizona.

Mr. Robert W. Hunt, consulting engineer, of Chicago, was awarded the John Fritz medal for 1912. This award is given "to commemorate notable scientific and industrial progress," and is made annually.

Dr. Richard L. Moore, physical chemist of the Bureau of Mines, is now stationed at the branch office, 502 Foster Bldg., Denver, Colo. Other members of the staff attached to the same office are Karl L. Kithil, mining technologist; J. C. Roberts, mining engineer in charge of the rescue car, and John A. Davis, mining engineer.

Mr. J. Wilson Nevius, representing the Los Angeles Chamber of Mines and Oil, has been making a study of the bag-house system of fume control at the smelter of the Mammoth Copper Mining Company, Kennett, Cal.

Dr. Jos. W. Richards, of Lehigh University, sailed with Mrs. Richards on December 21 for Jamaica, for a few weeks' vacation.

Mr. B. Viola, formerly managing and chief engineer of Charles Pfizer & Co., has opened a consulting engineer's office at 140 Liberty Street, New York City, for the installation and equipment of chemical and allied industrial works and power plants.

Mr. David White has been appointed chief geologist of the U. S. Geological Survey, vice Waldemar Lindgren, resigned. Mr. White has been in the Survey since 1886, and has had charge of several departments of the work. Dr. F. L. Ransome will succeed to the duties of Mr. Lindgren, in the economic geology of metalliferous deposits. Mr. Lindgren will be retained by the Survey for special work in a study of the Hone-stake mine, South Dakota, and at other places in Arizona.

Mr. C. E. Whittlesey, treasurer of the McGraw Publishing Company, celebrated his seventieth birthday on December 14, 1912. On this occasion he was entertained at luncheon at the Engineers' Club by his fellow directors of the McGraw Publishing Company and was presented with a silver salver as "a tribute of esteem and affection." Mr. Whittlesey, be-

sides being the treasurer of the McGraw Publishing Company, has been the treasurer of the Electrochemical Publishing Company, the former publisher of METALLURGICAL AND CHEMICAL ENGINEERING, from its early days. All the members of the staff of this journal are indebted to Mr. Whittlesey for innumerable kind words and acts of advice and encouragement, and join his many other friends in extending to him their most cordial wishes.

Digest of Electrochemical U. S. Patents.

Prior to 1903.

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

ORE TREATMENT (Continued).

629,685, July 25, 1899, Carl Hoepfner, of Berlin, Germany.

Relates to a process for electrodepositing zinc or other metals in solution by using an insoluble anode or an anode of a metal electronegative to that to be deposited, preferably lead, copper or mercury or the compounds of such metals, such as the sulfid or an argentiferous sulfid of lead, the silver, etc., remaining undissolved as a sludge. These compounds are either cast into bars, etc., or may be placed in a wire basket holder, etc. The anodes should preferably be kept in motion. The cathodes, which are also kept in motion, consist of carbon or of the metal to be deposited. The apparatus consists of a series of U-shaped frames bolted together and separated by diaphragms, forming separate cells, alternate cells constituting anode cells, and the intermediate ones the cathode cells. Communication between like cells is established by passages in the walls of the frames. The anode electrolyte is an acid in which the anode metal is soluble or a salt containing such acid as its radicle. The cathode electrolyte is any solution containing the metal to be deposited, such as zinc, iron, nickel, copper, etc. Both electrolytes are preferably heated and kept in constant circulation through the cell. The lead or other metal dissolved from the anode is precipitated outside of the cell as an insoluble compound, from which the metal may be reduced by smelting. The solution of the metal as anode will generate an electromotive force and to that extent reduce the electromotive force ordinarily applied to the cell.

629,686, July 25, 1899, Carl Hoepfner, of Frankfurt-on-the-Main, Germany.

Relates to the extraction of zinc or zinc and other metals from ores of the Brokenhill type and also of the Leadville Colo., type. Refers to his patent No. 664,269. The process consists in reacting upon a crude zinciferous sulfid mineral containing also other metals, as lead and silver, with a suitable chlorid solution, as cupric or perchlorid of iron, extracting a portion of the lead, removing the solution and roasting the undissolved residue; reacting upon this residue with hydrochloric acid as in the presence of water or a chlorid solution from a prior treatment, dissolving first the lead and silver and finally obtaining a solution of zinc chlorid, which is electrolyzed first with a low electromotive force to remove the electronegative metals present, gradually raising the electromotive force to successively precipitate the intermediate metals and finally precipitating the zinc; the electrolyte may now be used in the hydrochloric acid gas extraction.

631,040, August 15, 1899, John E. Greenawalt, of Denver, Colo., assignor of one-half to William Robinson, of same place.

Relates to the extraction of gold or silver from their ores. The ore is crushed to 20 to 30 mesh and subjected to a chloridizing roasting, after which it is placed in a vat having a bottom made of slats covered with a perforated board; above the board is placed a gravel bed, the coarser stones at the bottom and smaller ones at the top. Upon the small stones is placed the ore. A leaching solution consisting of a nearly saturated solution of sodium chlorid with some bromine is

electrolyzed in the anode compartment of a cell, producing free chlorine and hypochlorous acid and free bromine. This solution is used to leach the ore and is then passed through an electrodepositing cell using lead cathodes with a current density of about 0.07 amp per square foot of cathode surface.

633,544, Sept. 19, 1899, Harry S. Badger, of Denver, Colo., assignor of one-half to Charles W. Caryl, of same place.

Relates to apparatus for extracting and amalgamating precious metals. A suitable tank is provided with a central hollow vertical shaft having hollow horizontal cross-arms at the bottom thereof, the cross-arms carrying hollow stirrers with openings at the bottom. The vertical shaft is arranged to be rotated, is connected to a supply of compressed air and is connected so that the horizontal cross-arm is the anode. On the bottom of the tank is a copper plate flooded with mercury, connected as cathode. The pulverized ore is added to a solution of cyanide of potassium and such other reagents as facilitate the dissolving of the precious metals. The rotating stirrers and compressed air keep the ore in a state of suspension and leave the mercury free for the amalgamation and electrodeposition of precious metal.

639,579, Dec. 19, 1899, John Jones, of East Melbourne, Victoria.

Relates to the recovery of zinc from its ores. The ore is first roasted to sulfate, sulfite or oxid, leached by water or acid and the solution obtained freed from iron and other impurities, which is effected by flowing the solution down through absorbing towers through which is passed upward a stream of ammonia-containing producer gas, which operation is regulated so that the zinc remains in solution while the iron, etc., is precipitated. The purified solution is then acidified with sulfuric acid in a separate vessel and again passed through an absorbing tower through which is passing additional ammonia-containing producer gas. The purified producer gas may be used for fuel, etc. The zinc-sulfate ammonia-sulfate solution is passed into the anode compartment of an electrolytic cell, while an acidified zinc-sulfate ammonium-sulfate solution passes into the cathode compartment. In order to prevent the catholyte from becoming neutral or alkaline it is constantly acidified either by free acid or by circulating the anolyte through the cathode compartment. Any manganese salts in the solution are precipitated in the anode compartment by a suitable reducing agent.

639,766, Dec. 26, 1899, Lewis E. Porter, of Los Angeles, Cal.

Relates to rotary amalgamating barrels for extracting precious metal from base ores. The rotary barrel has an amalgamating cathode lining, either of removable plate, or by first copper-plating the inside, and then amalgamating. Adjacent the cathode is a diaphragm lining of burlap, etc., secured between a double layer of wooden slats. The anode consists of a series of carbon plates supported upon spiders, and are concentric within and rotate with the barrel. An adjustable valve, adapted to be automatically opened as the barrel rotates, affords an exit for any excess of gas pressure generated during the operation. The pulp mixed with the desired chemicals is fed into and removed from the space within the diaphragm through a removable closure in the end of the barrel; during the operation, compressed air is forced into the barrel through a hollow shaft, the air assisting in forcing the liquid through the diaphragm, and of acting as an oxidizing agent. Refers to a co-pending application filed Aug. 18, 1896.

640,717, Jan. 2, 1900, Charles P. Tatrow and George Delius, of Seattle, Wash., assignors to Harry S. Sharpe, of same place.

Relates to an apparatus for extracting precious metals from ores. The apparatus comprises a tank having a rotary drum supported on a shaft within the tank; a series of fixed carbon bars serving as an anode around the drum, a rotary stirrer within the tank below the anode, and a conical bottom containing mercury to amalgamate any large pieces of gold, etc., that may be in the ore. The pulp, mixed with a suitable solvent, is fed into the tank, the drum rotated and current turned on. The rotating stirrer keeps the ore in suspension, while the dissolved metals are electrodeposited upon the drum, from which

they are removed by a scraper pressing against the upper surface. After the operation is completed, the pulp and mercury are removed, the mercury is then retorted or otherwise treated to remove any precious metal. Refers to a co-pending application (patent 640,718) for the process.

640,718, Jan. 2, 1900, Charles P. Tatrow and George Delius, of Seattle, Wash., assignors to Harry S. Sharpe, of same place.

Relates to a process for extracting precious metals from ores. Refers to a co-pending application (patent 640,717) for the apparatus used. The ores are pulverized to pass an 80-mesh sieve, the pulp mixed with a bath comprising an aqueous solution of common salt, and such reagents, as lime, to precipitate the baser metals, such as iron, while leaving the precious metals in the solution. With some ores, an acid bath is first used to dissolve a particular base metal, which is then precipitated by an alkali. A small per cent of bromine may be added to facilitate the solution of the gold. The precious metal is electrolyzed and recovered as described under patent 640,717.

641,571, Jan. 16, 1900, Wilhelm Witter, of Hamburg, Germany.

Relates to the production of a solution of cyanogen halide, such as chloride or bromide, for the extraction of precious metals from their ores. A solution containing an alkali halide, such as chloride or bromide, an alkali cyanide, and a magnesium salt, is electrolyzed in a cell without a diaphragm and with inert electrodes, such as carbon. The solution produced contains cyanogen halide. The following equation expresses the reaction:

The magnesium salt and alkali cyanide are used in excess of the molecular proportions. The reaction may be carried out in the leaching vat direct in the presence of pulverized ore.

643,096, Feb. 6, 1900, Samuel B. Christy, Berkeley, Cal.

Relates to the electrolytic precipitation of gold and silver from the large volumes of dilute solutions of alkaline cyanides resulting from the cyanide extraction of gold and silver ores, etc. Uses a tank containing a large number of removable electrodes; the tops of the anodes remain about an inch below the solution level, and divide the tank into a number of separate compartments; between the anodes are the cathodes which project above the solution level, but leave a space of about an inch between them and the bottom of the tank. The liquid is electrolyzed while flowing through the tank, between the electrodes, above the anodes and below the cathodes; the deposit upon a number of cathodes being subsequently redissolved as an anode in a smaller cell, and deposited upon a single smaller cathode, thereby reducing the quantity of base metal to be separated from the gold.

649,151, May 8, 1900, William Wright, New York, N. Y., assignor by mesne assignments, of eleven-twentieths to William Bouldin, trustee, of Orange, N. J.

Relates to an apparatus for extracting metals from refractory ores, and comprises a leaching tank having a perforated false bottom, a filtering medium over the perforated bottom, a cathode within the space below the false bottom, a plurality of stationary pins arranged in concentric circles projecting upwardly from the false bottom, a rotatable shaft supporting radial cross-arms from which carbon anodes are suspended and arranged in concentric circles intermeshing the upwardly projecting pins. In operation, about 2000 lb. of ore are mixed with 1200 lb. of water containing from 20 to 40 lb. of common salt. The rotation of the anodes keeps the mass in constant agitation, the current liberating chlorine and decomposing the ore, the metals dissolved being deposited upon the cathode beneath the false bottom.

650,646, May 29, 1900, Frederic H. Long, Chicago, Ill., assignor to Ross J. Beatty, trustee, Muncie, Ind.

Relates to an apparatus for electrolytically treating ores, and comprises mixing, reducing, and filtering tanks; within the former the pulp is thoroughly mixed to a sludge with the electrolyte; the mixture is then transferred to the reducing tank, which consists of a circular vertical tank containing an upper

anode compartment and a lower cathode compartment, separated by a cone-shaped filter; centrally within the tank and communicating with the anode compartment is an upright penstock containing a reciprocating piston, which causes a circulation of the sludge through the anode compartment and penstock. During this circulation the ore passes the anode and is subjected to the action of the chlorine there liberated, whereby the metals are dissolved and then electrolytically deposited upon the cathode, which may be mercury. The base metals in the anode liquors may be precipitated as hydroxides by lime. Any gases liberated are fed into the mixer, where they assist in dissolving the metallic content of the ores. After the treatment, the sludge is transferred to the filter in which the liquid is separated for re-use or recovery of any remaining metallic salts.

BOOK REVIEWS.

The Principles of Applied Electro-Chemistry. By A. J. Allman, D.Sc. $5\frac{1}{2} \times 8\frac{1}{2}$ inches ($14 \times 21\frac{1}{2}$ cm.), 547 pages, 136 illustrations; price \$5.00. New York: Longmans, Green & Co. London: Edward Arnold.

A volume designed for students and technical men. Assuming an elementary knowledge of chemistry and electricity, Part I, 192 pages, treats of the fundamental phenomena and theory of electrochemistry, particularly of aqueous solutions. Part II treats of the various technical processes, from the standpoint of showing the close connection between theory and practice, treating the material critically, and excluding mere "paper" processes.

The author has succeeded in producing a valuable book; comprehensive, clear, fair and making full use of the copious electrochemical literature to date. To give a catalog of the subjects treated is unnecessary; it covers practically the entire field of inorganic electrochemistry. Organic electrochemistry is not included.

We commend the book as valuable to students and technical men. It is the equivalent of Haber's "*Grundriss der technischen Elektrochemie*," in English, revised to date, and improved upon.

* * *

Cyanide Practice. By H. W. MacFarren. 8vo ($15\frac{1}{2} \times 23\frac{1}{2}$ cm.), 291 pages, 32 illustrations; price \$3.00 net. New York: McGraw-Hill Book Company.

The basic idea of this book is not to treat exhaustively every detail of the cyanide process, but to give a bird's-eye view of the whole field, explaining clearly the principles involved in each step and giving sufficient detailed information to illustrate the principles. Description of variations of details at different plants is not attempted. The object thus in view is to bring the student or practitioner to the point of understanding thoroughly the process as a whole, and of being prepared to study more in *extenso* any branch of the process. To assist in the latter a very complete bibliography (of English literature only), covering 55 pages and divided into 33 heads, gives abundant information. It is a carefully prepared book and accomplishes its avowed object.

* * *

Per-Acids and Their Salts. By T. Slater Price, D.Sc. Six by 9 in. ($15 \times 22\frac{1}{2}$ cm.), 123 pages; price \$1.00 net. New York and London: Longmans, Green & Company.

This is the second of the Monographs on Inorganic and Physical Chemistry, which Dr. A. Findlay is doing the great service of editing and publishing. Modern scientific literature really needs only two classes of books: brief syllabi of an entire science, setting forth clearly principles and describing their application in the fewest possible words and comprehensive monographs going into great detail on the various branches of the science. Such must be the program of future scientific literature; the day of the vast encyclopedia of science which covers in one work all science or all of a science in all its details is rapidly passing.

The present book is a good illustration; it gives more precise, detailed, satisfactory information about per-acids and their salts than can be found anywhere else. Just as we go to an expert oculist or dentist for advice about eyes or teeth so must we turn to just such books as this for the best information about a special subject in science.

Dr. Price has done his work well; one has only to read a little in it, anywhere, to get that feeling of satisfaction which comes from the realization that the author knows all about all he is discussing. "May his tribe increase."

* * *

Theoretical and Physical Chemistry. By S. Lawrence Bigelow, Professor of General and Physical Chemistry, University of Michigan. Octavo (14×21.5 cm.), 544 pages, 80 illustrations; price \$3.00. New York: The Century Company.

Intended to lead third-year students in college or university to "a critical consideration of these half-learned, three-quarters forgotten, fundamental principles"; and recommended as following first courses in general chemistry and qualitative analysis. The author very concisely divides the book into four parts: "The first section (three chapters) aims to show the value of philosophy in science. In the second section (seven chapters) the ever-present question is: What are the ultimate constituents? In the third section (nine chapters) we are, primarily studying the properties of substances as such. In the last section (eleven chapters) attention is centered upon the processes by which substances become what they are."

The book is written with great care, clearness and insight. It is just the kind of text-book that would engage and hold the student's attention. To one not a student it appears in places to lack candor; that is, not to get down close enough to simple reasoning from observed facts, and at others to state conclusions on insufficient evidence. In all teaching conclusions should be given their exact values, and never overdrawn; thus, only are students taught exact thinking and reasoning. However, this book is above the average in these respects.

* * *

Church's Laboratory Guide. Revised and largely re-written by Edward Kinch, formerly Professor of Chemistry, Imperial College of Agriculture, Tokio. Ninth edition, 12mo (12×19 cm.), 368 pages, 44 illustrations; price \$2.50 net. New York: D. Van Nostrand Company.

This is a complete course in chemical laboratory practice for agricultural students. Part I comprises 39 lessons in elementary chemical manipulation and experimenting, chosen with discrimination and excellently presented. Part II is a short course in qualitative analysis, also well compiled and written, but necessarily very brief. Part III introduces the student to quantitative analysis, and after a short introduction takes up at some length the analysis of manures, soils, waters and foods. For the student in an agricultural college who does not intend to become an agricultural chemist, the book appears a most excellent laboratory manual; the agricultural chemist, however, should lay broader foundations in both qualitative and quantitative analysis than are to be gotten from this book.

* * *

General and Industrial Inorganic Chemistry. By Dr. Ettore Molinari. Translated from third Italian edition by Dr. E. Feilmann. Large octavo ($15 \times 25\frac{1}{2}$ cm.), 704 pages, 283 illustrations; price \$6.00 net. Philadelphia: P. Blakiston's Son & Company.

The author is professor of industrial chemistry in Milan, and has written this treatise for the use of students in order to bring before them the applications of chemical principles in industry simultaneously with the comprehensive study of the principles themselves. He assumes some knowledge of the elementary facts of chemistry and physics, but gives in the first 125 pages his own summary of chemical and physical principles. This is commendable, because it forms a connecting link with the students' preparatory studies, and further teaches him the author's point of view of these elementary

laws. Then the author proceeds systematically with the preparation in the laboratory and the manufacture on a large scale of the various non-metallic and metallic elements and compounds.

A distinguishing feature of the treatment is the setting forth, as clearly as possible, of the commercial side, including prices, statistics and commercial considerations. This is intended to give the student the business side of industrial chemistry, so that when entering the industry he may not be ignorant of the elementary financial foundations of manufacturing chemistry as a business and of the values and prices of the materials he uses and produces. It will make an excellent up-to-date text-book for students in chemical engineering.

* * *

Lead Poisoning and Lead Absorption. By Thomas H. Legge, M.D., and Kenneth W. Goadby. 8vo (15x21½ cm.), 308 pages, 15 illustrations; price, \$3.50 net. New York: Longmans, Green & Co. London: Edward Arnold.

The senior author is government medical inspector of factories in England; the junior author is surgeon to smelting and white-lead factories in London. The work covers the symptoms, pathology and prevention of lead poisoning, with special reference to its industrial origin and the processes involving this risk. The inhalation of lead dust is cited as the main cause, and exhaust fans, hoods or vacuum cleaners are named as the simple means by which the dust can be removed and the worker's health assured. The work is written in a highly scientific and exact style, using accurate medical phraseology. This makes it very satisfactory as a medical monograph, but limits its usefulness as respects the general reader. Every manager of works manufacturing lead products should be provided with the book, study its statements and follow its recommendations.

La Cementazione dell'Acciaio. By Dott. Federico Giolitti, Professor of Metallurgy in the Royal Polytechnicum of Turin. Octavo, 16x25 cm., 506 pages, 155 illustrations. Turin: Unione Tipografico-Editrice Torinese.

This brilliant Italian savant left the University of Rome two years ago to build and assume charge of the finest metallurgical laboratory in Italy, at the Polytechnic of Turin. The above work may be regarded as the first fruits of his labors and those of his students in this new chair.

There exists in no other literature so complete and masterly a study of the cementation process of manufacturing steel. It bears throughout the personal imprint of the enthusiastic investigator and able writer. Visiting his laboratory in Rome three years ago, we were wonderfully impressed by his enormous activity and the wonderful program of matters to be studied out when he should get into his new laboratory at Turin. Fortunate, indeed, is Italy in having such a professor and doubly fortunate those Italian students who have the inspiration of working under him.

As for the program of the book, 250 pages, divided into five chapters, deal with research into the chemistry of cementation. The contents of these chapters are: Early researches; up to the end of the XIXth century; the first seven years of the XXth century; the last five years; actual state of our present knowledge. In this section the author relates at length his own exhaustive investigations on the chemistry of the process, much of the information being here published for the first time.

In the second half of the book the industrial applications of the cementation process are discussed in a similarly thorough manner. The five chapters deal with: Total transformation into hard steel, partial transformation into hard steel (case-hardening), sub-divided into treatment by solids, liquids, gases, mixed agents and special agents, thermal treatment of cemented products; methods of control of the cementation; contents of patents on cementation. In this part the furnaces are illustrated by photographs and working drawings, and the author gives details of practice in various countries—American practice being well described.

We congratulate the indefatigable and genial author and also

his country on such a fine contribution to scientific literature and progress. Surely this is a victory of peace.

Coal: Its Composition, Analysis, Utilization and Valuation.

By E. E. Sommermeier, Professor of Metallurgy, Ohio State University. Octavo, 15½ x 23 cm., 175 pages, 8 illustrations. Price \$2.00. New York: McGraw-Hill Book Company.

The book has been prepared for the mechanical and power-plant engineer, the chemical engineer and chemist, and business men and operators buying and selling coal. The author has met this rather difficult program in a satisfactory manner.

The chemical part has particularly attracted our attention, by its very clear exposition of chemical principles and details involved in the analysis and combustion of coal, including a number of new and original points of view and calculations. There are full detailed directions for sampling, getting heat-values in calorimeters, analyzing flue-gases and interpreting the experimental results. The chapter on purchase specifications is short and condensed, but practical; it might have been amplified. About 300 analyses of coals, with calorimetric values, form a useful appendix. It is a well-written, useful and timely book.

* * *

Engineering and Metallurgical Books, 1907-1911. By R. A. Peddie. 206 pages, 4¾x7¾; \$1.50 net. New York: D. Van Nostrand Company.

A bibliography or catalog of the engineering and metallurgical books published in the years 1907 to 1911 inclusive. The books are classified under subjects, and a brief characterization corresponding to a sub-title is generally given. The names of both the American and English publishers are included and the prices in both British and American currency.

Apparently the work has been done with thoroughness and care, and will make a useful reference catalog for engineers and librarians.

* * *

Centenary Celebration of the First Commercial Gas Company. Lectures delivered at the Franklin Institute, Philadelphia, April 18 and 19, 1912. Octavo, illustrated; 174 pages. New York: The American Gas Institute, New York.

This book contains five carefully prepared lectures: By-Products in Gas Manufacture, by Prof. Charles E. Munroe; Commercial and Financial Aspects of the Gas Industry, by Hon. George B. Cortelyou; The Technique of Gas Manufacture, by Alfred E. Forstall, M.E.; Gas as an Illuminant, by Van Rensselaer Lansingh; The Use of Gas for Heat and Power and the Testing of Gas, by E. B. Rosa, Ph.D. Besides these first-class lectures there is a chronology of the use of gas, covering several pages, and description of an interesting Loan Exhibition.

The book is an appropriate and valuable souvenir of a dignified and memorable celebration.

* * *

Hygiene for the Worker. By Wm. H. Tolman, Ph.D., and Adelaide W. Guthrie. 12mo (12x18.5 cm.), 231 pages, numerous illustrations; price 50 cents. New York: American Book Company.

This inexpensive book is one of the Hygiene Series, edited by C. Ward Crampton. The authors are the Director of the American Museum of Safety and an assistant in the research department of that museum. It is intended for students in vocational, industrial and manual training schools and particularly for night schools.

An inspection of the nineteen chapters shows them to be carefully, accurately and attractively written, full of good common sense as well as of scientifically accurate information.

It is a good book to give to any worker, but particularly to the young; employers of labor may also find profit in reading it.

Metallurgical and Chemical Engineering

Chemists as Captains of Industry

Elsewhere in this issue we print a report of the presentation of the seventh impression of the Perkin medal to Dr. James Gayley at a joint meeting of the national chemical societies of this country, held under the auspices of the Society of Chemical Industry on January 29.

The award of the Perkin medal to one who has highly distinguished himself in applied chemistry, has now become a delightful annual event in chemical society and club life. The Perkin medal has become an inspiration to all who have at heart the future of American chemistry, and the Perkin medal has become an education for the general public as to the scope and achievements of chemistry.

Let other countries be proud of their warriors, poets, and musicians, the United States is proud of its great captains of industry, and the Perkin medal has become a means of proclaiming to all the world how many of the great captains of industry have been recruited from chemistry. Here is a list of those who have received so far the Perkin medal: Sir William Perkin, the inventor of the dyestuff mauve and founder of the coal-tar industry; Dr. J. B. Francis Herreshoff, to whom the general chemical industry of this country and electrolytic copper refining owes so much; Dr. Arno Behr, of the great American industry of corn products; Dr. E. G. Acheson, the founder of the carborundum and artificial graphite industries; Dr. Chas. M. Hall, the founder of the American aluminium industry; Mr. Herman Frasch, of oil refining and sulphur mining fame, and now, Dr. James Gayley, the inventor of the dry-blast process, who began as a simple steel chemist and grew to be the first vice-president of the U. S. Steel Corporation.

This is certainly a brilliant list of names and a brilliant list of achievements. And yet, lest we forget, that is only the beginning.

Empirical vs. Exact Methods

It has been remarked that the oldest mining districts are the most conservative, where progress and change are accomplished only by laborious effort on the part of outsiders. In such places it is not uncommon to find metallurgical operations based on empirical knowledge derived from limited observation. The natives rely with satisfaction on tradition and custom, and rest contentedly on the use of inexact and unscientific methods without realizing their limitations. It is true that some empirical methods have a basis in fact and, in the hands of skilled operators and observers, serve a useful purpose. The control of the bessemerizing and poling of copper, and the estimation of the value of some gold-ores, are notable examples of arbitrary methods which, to the practiced eye, yield reliable results.

The vanning shovel is a device in the same class with the gold-pan. For years the practice of vanning has been

firmly entrenched in Cornwall as a method for determining the value of tin-ore and concentrate. The skill of the Cornishman with this device is proverbial. So great has been the reliance placed in the results obtained by the vanning shovel that the efficiency of milling operations and the buying and selling of concentrates are confidently based thereon, to the general exclusion of chemical methods of analysis.

There has been a growing suspicion that the vanning assay for tin is unreliable, together with a lack of confidence in the supposed efficiency of Cornish tin-milling when based on such assays. More recently this suspicion has been confirmed, and a rude shock given to the advocates of Cornish practice by one who has had an opportunity of studying the district and its methods. Fortified by the more exact methods of chemical analysis, this investigator has come to the conclusion that the vanning experts have been deceiving themselves as well as others; and that, so far from making a mill recovery of 90 per cent, the actual tin extraction throughout Cornwall to-day is between 50 per cent and 60 per cent. In competitive tests between the vanning assay and chemical analysis, the results of the former ranged from 22 per cent to 95 per cent of the latter, being more exact on high-grade coarse cassiterite.

In the light of these figures it seems almost incredible that a great industry should be controlled by such inexact methods; and more so that the custom should prevail in the face of better knowledge. The continuation of the practice in spite of the protests of those who are informed as to its deficiencies, shows how firmly rooted it is. Progressive metallurgists realize that the continued use of the vanning shovel is largely responsible for the backward condition of tin metallurgy in Cornwall, and they look for improvement in the latter as fast as accurate chemical analysis supersedes the arbitrary and inexact vanning assay.

Surface Quality in Steel

We have long been accustomed to think of quality in steel almost wholly in terms of elastic limit, yield point, ductility, hardness, resistance to fatigue, etc., while more lately we have had to consider, for certain classes of steel, magnetic permeability, hysteresis, conductivity, etc., and for certain other classes of steel the question of corrodibility has been emphasized by some producers.

A somewhat new factor has been looming large of late, on account of the extremely rapid increase in the use of steel sheets for metal furniture and for various automobile parts, particularly bodies and hoods. These sheets are required to take a high degree of finish. Various finishes are furnished by the sheet mills, leaving the surface in condition to take such coating as the fabricator desires to apply. It has been found that these so-called "finishes" given by the mill are not to be regarded purely as treatment superficial or entirely subsequent to the manufacture of the steel sheet. The character of the steel itself is found to have much to do with success in applying the "finishes." There is practically no literature on the subject.

The mills which have developed these finishes most successfully have not taken the public into their confidence. They have been learning rapidly, and the information has

not had time to percolate, but it has become perfectly clear that to our researches as to how to make steel strong, ductile or hard as the case may be, qualities which are purely of cross section, there must be added study as to how to make steel such that it will present, or yield itself to being given, a particular character of surface. This is practically a new field in the adaptation of steel to commercial use. The first man who modified the character of steel in order to contribute to surface finish has not come forward to claim the honor, preferring to endeavor to maintain a commercial secret, but we have reason to believe that what he did was done only very recently.

Technical Education

University extension courses of study have developed a successful means of disseminating knowledge on many subjects. Short courses in agriculture have proved valuable for farmers, being given during the winter months when work on the farm is not pressing. Correspondence courses in a variety of subjects have served a useful end. Reasoning by analogy, it has been suggested that "practical" short courses in mining and milling, given by professional schools of mines, might be beneficial in raising the standard of work in those industries. The proposal raises a question on which there is a wide difference of opinion.

Recently the University of Tennessee has announced extension courses, designed especially for workers in mining and quarrying. Physics, chemistry, mathematics, geology, mining, metallurgy and mechanical engineering are the subjects touched upon during a short course of six weeks duration, supplemented by correspondence work. The object of the course is to afford an opportunity to the man "on the firing line" to improve his work by the understanding of scientific principles. Another school, at Platteville, Wisconsin, has for its aim the training of young men in the practical details of mine and mill work, without pretending to turn out finished engineers. This training school produces technicians, but not technologists.

The principal argument in favor of the short course is that it renders a distinct service and ultimately raises the standard of work. There are, perhaps, stronger arguments against the short course in professional mining schools. Alumni almost a unit against the plan, believing that it would detract from the reputation of the school, and affect their prestige as graduates. The difficulty arises of differentiating for the public between engineering graduates and short-course students. Each might, with varying degrees of propriety, claim attendance at a well-known school; but without further explanation, the short-course student would give the inference that he was on a par with the engineering graduate. Even if such a result were not intentional, it is a possibility.

Except for instances in which local conditions seem to favor the short course, it would seem better to maintain the integrity of the school of technology, and leave the other field for the strictly training school.

The Digest of U. S. Electrochemical Patents

When this journal was started somewhat over ten years ago with the title "Electrochemical Industry," analyses of current electrochemical U. S. Patents naturally suggested

themselves as valuable, instructive, and interesting news matter. At the same time it was obvious that for anybody who wants to look up the patents on a certain subject, it would be very important to be able to find also the older U. S. patents which had been issued before this journal was started. This consideration suggested a new department—one decidedly unique in technical journalism—the "Digest of Electrochemical U. S. Patents prior to 1903, arranged according to subject matters and in chronological order."

For the preparation of this department this journal had the good fortune to secure the services of one most competent to do the work—Dr. Eugene A. Byrnes. And the Digest, prepared by Dr. Byrnes, has been published regularly ever since. It has been used extensively by those who understand its scope and object. But the fact that the subscription list of this journal has increased very rapidly in recent years far beyond the limits of the original constituency, suggests that to many of our more recent friends the idea of the Digest may not be sufficiently familiar and to them a concise summary of the immense amount of work of love stored up in this department in the past ten years should be welcome. This also gives us an opportunity to say a word on electrochemical U. S. patents in general.

When Dr. Byrnes was appointed principal examiner of Division 3, "Metallurgy," etc., in April, 1891, the comparatively few U. S. patents theretofore granted relating to electrochemical subjects were scattered through several different divisions and subclasses of the Patent Office, especially through Division 3 with classes on metallurgy, coating with metals, and distillation; Division 6 with classes on bleaching and dyeing, chemicals, hides and leather, and medicines; Division 25 with a class on paper making (bleaching); Division 26 with subclasses on batteries for the generation of electricity.

As the art of electrochemistry was then becoming quite active, it seemed desirable to collect these scattered patents into a single class, and Dr. Byrnes suggested to the Commissioner of Patents that such class be established under the title "Electrochemistry." Some argument was necessary to convince the Commissioner as to the need for this class, and the propriety of such title. However, in view of favorable recommendations of other examiners, and the fact that the word "electrochemistry" had been used to a slight extent by others, having been adopted by Becquerel as the title of his classic book, while the first edition of Borchers' "Elektro-Metallurgie" had just appeared, the Commissioner ordered the establishment of the new class, in May, 1892. The 390 patents which Dr. Byrnes had collected for this class were distributed into 27 subclasses, being, with two exceptions, those of the present classification.

On December 27, 1892, subclass 28, Diaphragms, was established, and the patents on batteries were received from Division 26, where they existed as subclass 6, "Batteries, Galvanic" and 72, Batteries, Secondary." On November 23, 1894, subclass 31, "Synthesis" and 32, "Synthesis, Ozone" were established, the old subclass 23, "Ozone," being abolished. The subclass of "Galvanic Batteries" was split up, prior to January 1, 1895, into subclasses 33-53, first published in the Official Gazette of that date. On January 31, 1897, new battery subclasses, 53-56, were established; also the following: 57—Refining Metals; 58—Chemicals. Alka-

lies and chlorine; 59—Chemicals, Bleaching and disinfecting liquors; 60—Chemicals, Chlorates; 61—Chemicals, Dyes and pigments; 62—Synthesis, carbides; 63—Reduction; 64—Electric furnaces; the old subclass 2, "Bleaching" being abolished. There has been no subsequent change in the classification of these patents.

At the date when Dr. Byrnes began to analyze these patents for the Digest in this journal, July 1, 1902, ten years after the class had been established, the number of electrochemical patents, aside from those on batteries, had increased from 390 to 1486; and on December 10, 1912, the number had increased to 3498.

The Digest, so far published, has covered the more important patents prior to 1903 according to subject matters in chronological order as follows:

Electrolysis of sodium chloride with mercury anodes (vol. I, p. 42, 78).

Diaphragm cells for the production of caustic alkali (vol. I, p. 114, 152, 196, 232, 268, 300, 340).

Bleaching and disinfecting liquids (vol. I, p. 368, 401, 433).

White lead by electrolytic methods (vol. I, p. 474, 518).

Dyes and Pigments (vol. I, p. 518, 555).

Chemicals (vol. I, p. 598; vol. II, p. 43, 80, 123).

Production of aluminum from molten electrolytes (vol. II, p. 165, 210, 253).

Production of sodium from molten electrolytes (vol. II, p. 296, 333, 384, 434).

Molten electrolytes, Miscellaneous (vol. II, p. 434, 474, 517; vol. III, p. 48, 88).

Electric Smelting and Reduction Furnaces (vol. III, p. 128, 164, 208, 246, 284, 322, 362, 406, 448).

Treatment of carbon and the production of graphite (vol. III, p. 482; vol. IV, p. 42).

Production of nitrogen compounds (vol. IV, p. 80, 120).

Production of ozone and miscellaneous gas reactions (vol. IV, p. 162, 204, 252, 290, 338, 423, 468, 514).

Carborundum (vol. V, p. 36, 70, 108).

Calcium carbide (vol. V, p. 154, 198, 248, 292, 336, 382, 430, 480, 516; vol. VI, p. 39, 86, 132, 170, 218, 264).

Electric furnaces (vol. VI, p. 306, 345, 389, 434, 476, 523; vol. VII, p. 49, 97, 140, 176, 235, 293, 373, 413, 459, 499).

vol. VIII, p. 57, 168, 216, 305, 380, 553, 605, 653, 706; vol. IX, p. 58, 116).

Ore treatment (vol. IX, p. 166, 230, 285, 333, 382, 420, 560, 618, 684; vol. X, p. 62, 122, 188, 322, 446, 502, 570, 704, 765, 825; vol. XI, p. 59).

After completion of the patents on Ore Treatment the following subjects remain to be taken up in the Digest: Refining metals (subclass 57); Plating, ornamenting, electrotyping, production of articles, and miscellaneous applications (subclass 1-8, 10-14 and 16-18); Diaphragms (subclass 28); Purifying liquids (subclass 24-26); Tanning (subclass 27).

With the continuously and rapidly increasing importance of electrochemical methods in so many fields of chemical, metallurgical and industrial endeavor, it becomes daily more and more important to be able to find out quickly what was already known in the early history of electrochemistry. Nothing is more convenient or better accessible to supply such information than Dr. Byrnes' Digest covering the field completely and concisely in the volumes of this journal.

Readers' Views and Comments

In Memoriam—Henry de Mosenthal

To the Editor of Metallurgical & Chemical Engineering:

Sir:—In the history of the modern explosive industry a chapter has been closed by the death of Henry de Mosenthal on the 17th of December last from heart failure. Even only a short sketch of his life and work should prove a source of inspiration.

Henry de Mosenthal was born in 1850 at Port Elizabeth, South Africa. He had been associated with Alfred Nobel, the inventor of dynamite, for some years before the formation, in 1886, of the Nobel Dynamite Trust Company, Ltd., of which he was appointed technical secretary from the very first. This position he held until his death.

He was a well known figure in the explosives industry of the world, and his business wisdom and great ability earned for him a high reputation in the business world and in the industry with which he was more especially connected.

De Mosenthal was a Fellow of The Institute of Chemistry of Great Britain and Ireland for twenty years and served for two periods of three years as a Member of the Council. He also belonged to the principal chemical and scientific societies, and will be remembered, not only on account of his connection with the manufacturing aspect of the explosives industry, but also for his valuable scientific work.

Most of his researches were contributed to the *Journal of the Society of Chemical Industry*, and among these may be mentioned the following:

1894, Vol. 13, p. 326—"Treatment of Gold Ore at the Witwatersrand (Transvaal) Gold Fields."

1899, Vol. 18, p. 443—"The Life Work of Alfred Nobel."

1904, Vol. 23, p. 292—"Observations on Cotton and Nitrated Cotton."

1907, Vol. 26, p. 443—"Observations on Cotton and Nitrated Cotton."

1911, Vol. 30, p. 782—"Observations on Cotton and Nitrated Cotton."

The subject of Alfred Nobel was also treated in a biographical sketch in the "Nineteenth Century" of October, 1898, entitled: "The Inventor of Dynamite," and of course, de Mosenthal's intimate relations with Nobel enabled him to write a complete, and one might almost say, classical, biography of Nobel's life and work.

De Mosenthal also contributed articles on "Nitro-Glycerine and Nitro-Glycerine Explosives" and on "Permitted Explosives" to the work published by the explosives section of the Seventh International Congress of Applied Chemistry and entitled: "The Rise and Progress of the British Explosives Industry" (Whittaker & Co., 1909).

De Mosenthal was an expert in microscopy and micro-photographic work, and indeed the earliest of his papers, that on the treatment of gold ore, was already illustrated by micro-photographs. His technique, patience and manipulative skill enabled him to obtain the most remarkable results.

His researches on cotton and nitrated cotton were intended to obtain a picture of the constitution of the cellulose molecule, and he early recognized that the colloidal condition of the substances he examined necessitated methods other than those employed for bodies of a crystalline character. De Mosenthal accordingly determined values for a large number of the physical constants of cotton and of nitrated cotton, and these, together with his deductions, have thrown a good deal of light on this debated question.

In his first paper he was able to show the presence of stomata in the cotton fibre which had until then remained undetected. In his subsequent papers the effect of polarized light on nitrated fibres is described, and the connection between the degree of nitration and anisotropic effect criticised. The density of cotton and of nitrated cotton was determined, and an important difference was shown to exist between the increase

in molecular volume with ascending degree of nitration in the case of cotton, when compared with that afforded by the simpler alcoholic nitrates.

The refractive index was investigated, films of the nitrated cellulose being employed, and from the values obtained, the molecular refractions of the di- and tri-nitrates were calculated. The optical activity of nitrated cotton was examined, and its dextrorotatory character confirmed. Work on the dialysis of solutions of nitrocellulose in acetone ultimately established that the substance could not pass through a sound membrane: nor was it possible to detect any osmotic pressure.

In the last paper of the series de Mosenthal applied the results of his work to the nature of the constitution of cellulose, and stated his reasons for considering that it had an open chain structure. Whatever the view which will ultimately prevail, as to whether this or a cyclic constitution is the more rational, the values of the constants determined by de Mosenthal, the description of his methods, and his impartial discussion of the results, constitute a material contribution to the advancement of our knowledge on this difficult subject.

De Mosenthal's papers were the result of much care and infinite thought. It is characteristic that on the day before his death, he discussed his ideas and future programme of research, and it has been arranged that they shall form the subject of a scientific investigation by two of his friends and colleagues as tribute to his memory.

As an illustration of his great versatility it may be mentioned that apart from his scientific work, de Mosenthal published several monographs of a popular nature on explosives in which he exhibited to a remarkable degree his talent for popular exposition of abstruse technical subjects, and for making them understood by the general public. Some of these monographs appeared in the papers of the Savage Club, of which institution he was an esteemed member.

De Mosenthal was a bachelor and a remarkable linguist. He knew the four or five languages which he spoke with a thoroughness as though each was his own, and in addition, he possessed the rare faculty of immediately grasping the vital point in a controversy. He was a trenchant, fearless, yet kindly critic, and he will be sorely missed by a wide circle of friends and colleagues whom it is not an exaggeration to say he could count in every quarter of the globe.

—A FRIEND.

The Tungsten-Molybdenum Thermo-Couple

To the Editor of Metallurgical and Chemical Engineering:

Sir: Permit me to correct the rather surprising claim made by Edwin F. Northrup, Ph. D., in your January issue, p. 45, to the effect that he was the one who first suggested this couple at a recent meeting of the Philadelphia Branch of the A. I. E. E. I am sure those present will recall, and if there had been a stenographic record it would certainly have shown, that the proposal to make a pyrometer of these two very infusible metals was made first in my discussion of the papers and not by Dr. Northrup, although he discussed the proposition afterwards together with several others, and told me after the meeting that the idea seemed interesting and that he would proceed to make a trial of one. He certainly did not mention the couple before I rose to suggest it, for if he had there would have been no object in my doing so.

One of the members, in reply to my discussion, stated that he had tried it and had found that there was no e.m.f.; but after the meeting he explained to me that what he had tried was not a couple of these two metals, but something different, namely one between tungsten and some metal other than molybdenum.

After someone has contributed publicly to the profession a suggestion which appears to be of value to his colleagues, it is

almost invariably the case that claimants of priority at once come forth; it is then so easy to say that one had done a thing before others announced it, and even to manufacture alleged proofs; in such cases, inquiry generally shows that the alleged prior claimant had something different, probably just short of the successful element, which he then persuades himself to believe was the same, in order to take away the credit from the one who first contributed the suggestion publicly for the benefit of his colleagues, instead of secreting it for his own personal benefit. But whether it is the same or not, such practice should be discredited and looked down upon by the profession, and should be considered as not being in accord with professional ethics. The true professional spirit at such meetings is to exchange views, opinions and suggestions for mutual benefit, and if a member withholds, for his personal benefit, something which is of value to his colleagues (excepting, of course, patentable devices or trade secrets), he is not giving to others what he expects others to give to him at such meetings, and he should therefore be debarred by a code of professional ethics from making prior claims after some less selfish member had contributed it publicly to his colleagues. By secreting such matters one sacrifices his moral right to claim priority afterwards.

In his article Dr. Northrup did not give the complete description which I had given at the meeting. After I had suggested the couple of these two metals because they had a very much higher fusing point than the usual copper alloys and even cast iron and steel, and could therefore be inserted directly into the liquid metals, the question at once arose with what material the wires could be protected from direct contact with the fused metal with some of which they might alloy; one speaker asked me how to make "the hole in the liquid metal," and I then stated that I had found that electrically fused magnesite (which is on the market) withstood steel temperatures very well, and that I had seen tubes made of this material which seemed to me were not too porous. Graphite might answer in some cases.

Of course, such a protecting tube would be essential for the success of such a thermo-couple when it is to be used to plunge directly into the fused metal so as not to have to depend on measuring the temperature by radiation from the liquid surface, which in arc furnaces must necessarily be higher (and probably considerably) than the body of the liquid metal itself, or which in resistance furnaces in which the heat is generated in the liquid itself, would be lower than the metal or the important contact surface of the metal and the slag. In such a furnace the top surface of the slag might even be relatively considerably cooler although the active layer in contact with the steel may be very hot.

Besides this tube I also suggested placing in it some inert material which would either generate a gas which would be inert to the tungsten and molybdenum (hence non-carbonaceous) or would at least consume what little oxygen there was left in the tube, although if the wires were made thick enough that slight amount of oxidation might not be serious. I also suggested glazing the wires with some enamel, if such an enamel could be found.

Since Dr. Northrup found later on that the curve of this couple intersected the zero axis at 1060°C . (see his article) the question arose how a direct reading instrument could be used for a range to both sides of this zero value, as that is the very range for which this thermo-couple was suggested and would be most useful. I then suggested that either the "cold" end might be raised to some known high temperature, which presumably would shift this zero point to a less objectionable region, or an instrument of the Weston type with the point for no current in the middle of the scale, might be used. Apparently the only objection to this would be that up to 530°C . the readings would be wrong (unless indicated by a supplemental scale); but as such a couple would presumably be used only for red and white heats, the eye could be trusted to show whether the temperature was on the upward or downward part of that peculiar curve.

Such an instrument as that here suggested would be of considerable importance for use with furnaces for melting metals, which is the purpose I had in mind; and as it seems promising it is hoped that some enterprising maker will take sufficient interest in it to put it on the market.

Philadelphia, Pa.

CARL HERING

* * *

To the Editor of Metallurgical and Chemical Engineering.

Sir: After reading Dr. Northrup's article on page 45 of your January issue on "Tungsten and Molybdenum—Their Thermal E.M.F.," I feel that I owe it to the two other manufacturers of pyrometers, who contributed discussions at the meeting referred to, to exonerate them from the odium of making a statement not borne out by Dr. Northrup's subsequent experiment.

First, let me remark that while I made the statement quoted I did not put the emphasis where Dr. Northrup's italics put it. Indeed, the statement has been torn from its context and so given a scientific rather than its obvious commercial meaning. The suggestion of a tungsten-molybdenum thermo-couple was made by Dr. Carl Hering, who complained that makers of pyrometers had so far failed to provide any means of measuring the temperature at the bottom of a bath of molten steel. I stated that the Thwing radiation pyrometer had been used successfully for measuring these and much higher temperatures, and if he would find a tube which would have the necessary mechanical strength to withstand the pressure at the bottom of the bath, I would measure the temperature at the bottom of his tube with ease.

My strictures on the Mo-W couple were based, not alone on its oxidizability, but on rough determinations of the e.m.f. of each of the elements against iron, which showed at the melting point of iron an e.m.f. which was but a small fraction of that given by the platinum couple.

Dr. Northrup's more exact determinations would indicate an e.m.f. of about 3 or 4 millivolts, at 1500° or 1600°C ., which would be high temperatures for a bath of steel. This is but one-fifth that of a platinum couple, a fact which would doubtless cause this couple to be rejected by any maker of commercial pyrometers, even if it had the useful uniformity and durability.

In the course of two years devoted largely to the investigation of thermal e.m.f. of all obtainable metals and alloys, I could not have failed to discover what any physicist would have assumed a priori, namely, that any pair of elements would, at some temperature, give some e.m.f. Had Dr. Northrup had the courage to challenge my statement on the spot, he would have had his suspicion that there ought to be some e.m.f. confirmed by me, but, in that case, we might have been deprived of his prompt investigation of the problem, which I, for one, should have deplored. By all means let us find a thermo-couple which is good at 2200°C ., if there is one, not forgetting, however, to provide a suitable protecting tube at the same time. I have seen a lot of good platinum destroyed in tubes built of "hopes" much less ambitious than those of Dr. Northrup, all in a very short time after they were inserted in a bath of steel.

CHARLES B. THWING

Philadelphia, Pa.

Waste tin is an important by-product of the northwestern salmon canneries. Scrap tin is sent to Germany, where it is used in the manufacture of toys, and strip tin is shipped to California for use in the manufacture of fruit and berry boxes.

Beds of magnesite of good quality are said to exist in Lower California in the region of Magdalena Bay. Analysis shows these deposits to contain 92 per cent carbonate of magnesium. The largest bed, on Margarita Island, has an area of 30 acres. A company known as La Compania de Desarrollo y Explotacion de la Baja California, of San Diego, Cal., has been organized to exploit the deposits

The Western Metallurgical Field

Alaska

Considerable interest attaches to the proposed operations of the Alaska Gold Mines Co., which has recently taken several properties in the Juneau district under its management. A 6000-ton mill is to be built at tidewater, and a 5000-hp. hydroelectric power plant is under construction. The average grade of the ore is \$1.50 per ton, and the anticipated cost of mining and milling is placed at \$0.75 per ton. Comparison is made with the costs at the Alaska-Treadwell to show that a cost of \$0.75 for Alaska Gold Mines is not excessive. Thus, in 1911 the cost of milling at the Treadwell was only 22.52 cents for the 240-stamp mill and 18.20 cents for the 300-stamp mill. The Alaska Gold Mines' 6000-ton mill should equal these mills in point of cheap cost of operation, and consequently 25 cents is considered a fair estimate for this item. This would leave only 50 cents for mining and delivery to the mill, whereas the Treadwell cost for the same operations is about \$1. To explain this discrepancy, it is claimed that cost of mining the Alaska ore will not be nearly as great as that of the Treadwell, while the power cost will be limited to interest, depreciation and maintenance of the hydroelectric plant. The entire proposition is one which depends for success on the treatment of a large tonnage at a small margin of profit, and requires an enormous investment.

The value of the mineral output of Alaska for 1912 is estimated by the United States Geological Survey at \$21,850,000, compared with \$20,650,000 for 1911. The increase is to be credited to the larger copper production in 1912, as gold fell off slightly and silver was only increased by a small margin. The value of all other mineral products showed a slight increase. Information at hand regarding placer operations indicates that gold recovery from this source fell off during 1912; on the other hand, gold from lode mining increased.

There was no abatement in dredge installation on the Seward Peninsula in 1912. During the year 39 dredges were completed or in process of erection, and about 30 were in operation last August. It is significant that these dredges are scattered over the peninsula, in every district where placer gold has been discovered. It is assumed that the production of placer gold from the peninsula has passed its minimum for many years to come.

Revival of the Augustin Process

Fifty years ago the Augustin process of treating silver ores probably was more generally known than it is to metallurgists today. Chloridizing-roasting, leaching with salt water and precipitation of silver on copper formed the basis of the process. Recently a mill has been completed at Park City, Utah, by the Mines Operating Co., for the purpose of treating low-grade ore from the Ontario mine. The first experimental work on this ore indicated probable success with cyanidation, but later it was decided to use the other process mentioned. Details of operation at this particular mill have not been made public, but the revival of the old process is being watched with interest, and it is hoped that success will be achieved.

Mercury in 1912

Preliminary figures collected by H. D. McCaskey, of the United States Geological Survey, from the individual producers show that the domestic production of quicksilver in 1912 was 25,147 flasks of 75 pounds each, valued at the average San Francisco domestic price for the year, \$42.04, at \$1,057,180. A comparison of these figures with the final published Survey figures for 1911 and 1910 shows a gain over the output of 1911 of 3891 flasks and over that of 1910 of 4546 flasks. Twenty mines were reported as producing in 1912, of which 16 were in California against 22 producers in 1911, of which 19 were in California.

American Mining Congress

The work of the last session of the American Mining Congress is reflected in the large number of important resolutions adopted pertaining to the mining industry. There was a nota-

ble absence of formal speeches and technical papers, and a corresponding increase in debate on pertinent topics. Among the more important resolutions adopted were the following: Urging the immediate construction by federal aid of two trunk lines of railway from the Pacific coast of Alaska to the great navigable water systems of the interior; protesting against any reduction of the present tariff of zinc and lead; recommending state legislation making it a misdemeanor for any ore-buyer to mix or in any way disguise the identity of a lot of ore before its value has been definitely agreed upon by buyer and seller; urging Congress to provide for federal assistance to state schools of mines; commending Congress for its appropriation to the Bureau of Mines for investigations in metalliferous ores, and asking further increased appropriations; favoring the enactment of laws extending the principle of eminent domain to aerial trams, electric lines and pipe lines; asking the national government to assist in construction of roads through national forests; appointing a committee on mine taxation; suggesting to the President the appointment as Secretary of the Interior of a resident of the public land states, or one familiar with the public land laws.

Activity in Rare Metals

The uranium and vanadium districts of southwestern Colorado and southeastern Utah were the scene of considerable activity during the last year. An inspection of both districts gives the impression that Colorado contains smaller but richer deposits, while those of Utah are more extensive but not so high in grade. The General Vanadium Co. has purchased a large number of claims in Colorado, and has become one of the principal producers. It is difficult to give a statement of the production, as there are several small producers who sell their ores to larger concerns; but it is certain that more work was done and more ore shipped during the past year than ever before. The grade of the ore is generally low; the districts are isolated; transportation is difficult and expensive; and for these reasons development is slow. As the region is quite dry and streams are few and small, additional obstacles are placed in the way of local treatment plants. There is need for a successful system of dry concentration which will raise the grade of the ore and thereby reduce the expense of transportation and subsequent treatment. One new treatment plant was erected and placed in operation last year. It is situated in western San Miguel county, Colorado, near the junction of Disappointment creek and the Dolores river, where the Dolores Refining Co. originally had a mill.

Metal Production Statistics

The preliminary statistics of the United States Geological Survey on metal production in 1912 give some interesting comparisons with 1911. The gold mining industry was about normal, but early figures indicate the smallest production since 1907, when the output was worth \$90,435,700. In 1912 it was apparently \$91,685,168, or over \$5,000,000 less than in 1911. The decrease is ascribed mainly to Nevada, and particularly Goldfield, where the production fell off about \$4,500,000. A further decrease is noted in Colorado, particularly from the Camp Bird mine, although an increase was noted from the Cripple Creek district. The Survey has adopted the plan of distributing gold production under several heads, as placer, amalgamation, cyanidation, smelting, etc., but these figures are not yet available for 1912.

The output of silver was the largest in the past 20 years, amounting to 62,369,974 fine ounces. Only twice since 1892, namely, in 1893 and 1911, has the production been above 60,000,000 ounces, and it is expected that final figures for 1912 will show the silver production to have been the largest in the history of the country. The increase is attributed mainly to the notable increase in copper production from districts in which the ore also carries silver.

Copper production in 1912 was the largest in the history of the United States, and six of the copper producing states, namely, Arizona, Michigan, Utah, Nevada, New Mexico and

Alaska, have each exceeded all former records of production. According to the best figures obtainable, the copper production amounted to 1,249,000,000 lb. in 1912, an increase of over 140,000,000 lb. over 1911. Arizona again holds first place among copper producers, with Montana, Michigan, Utah, Nevada, California and New Mexico following in the order named.

The preliminary figures on lead show a slight decline from the high record of 1911, being approximately 480,965 short tons of desilverized, soft lead, not including antimonial lead. Spelter shows a remarkable increase, stimulated by the high prices for the metal. The production of primary spelter from domestic ore in 1912 is estimated at 323,961 short tons, and from foreign ores at 14,669 short tons, a total of 338,630 tons.

The production of tungsten is estimated at 1290 tons of concentrate carrying 60% WO_3 , an increase over 1911. Uranium and vanadium show an increase, although it is difficult to get exact figures. The uranium production is equivalent to 26 tons of uranium oxide, while the vanadium output is equivalent to 300 tons of metallic vanadium. Quicksilver showed the largest production in six years, being 25,147 flasks of 75 lb. each. The principal increase was in California; in Nevada there was a largely increased output.

The Iron and Steel Market

January has brought mixed developments in the iron and steel market, but on the whole the developments are much more favorable than there was reason to expect. The only development which can be considered really unfavorable is that crude materials, coke, ore, scrap and pig iron, have shown an easier market tone. This is not particularly unfavorable, for January normally is a quiet month for all these materials, and nothing approaching a slump has occurred in any of them.

In the steel market proper conditions are all stronger than at the close of December. It is true that there has been a decrease in forward buying of finished steel products, but this is a function of the distance ahead to which material was already sold. Some market judges appear to think the decreased volume of forward buying betokens uneasiness on the part of buyers because of the change in the national administration, involving the certainty of serious tariff revision among other things, but it is really very difficult to imagine that were this not the case, January would have seen heavy contracting all along the line for third and fourth quarter delivery. The contracting for first half had already been done.

There has been an accentuation of the pressure upon the mills for deliveries. This is seen in two ways. Buyers who had already specified for materials are strenuously representing to mills that they desire better deliveries. Again, there is heavier buying, of early deliveries and at larger premiums. The producing mills are distinctly divisible into two classes, those that sold far ahead upon contract at regular minimum market prices, and those (usually the smaller mills) which held aloof in the expectation of profiting by the premium market which has ruled of late. The strongest pressure is in plates. While the Carnegie Steel Company names a price of 1.45 cents on the limited class of orders it will accept, involving delivery far ahead, and large independents are naming 1.50 cents for somewhat similar delivery, the small independents are able to sell plates in carloads to 100 or 200 tons at 1.75 cents for delivery in four to six weeks, and in similar or larger lots at 1.60 to 1.65 cents for deliveries March to June inclusive. In merchant steel bars similar conditions prevail, and in sheets the character of the market is the same, though the premiums are hardly as large.

Production is at record rate, represented by pig iron being made in January at the annual average of 33,500,000 tons, nearly 4,000,000 tons in excess of the average during 1912, and with steel production proportionately increased. From physical considerations the output cannot be expected to be much larger than this, and under the most favorable market conditions conceivable the present year's production cannot be expected to be above 34,000,000 or 35,000,000 tons.

Pig Iron

Southern pig iron has distinctly softened, as prompt iron of many brands is readily obtainable at \$13.50, Birmingham, while some brands of Tennessee iron are purchasable on this basis for delivery two or three months ahead, and regular Alabama iron for second quarter may easily be had at \$14. This represents a clear recession of 50 cents on all positions. History shows that general advances and declines in the pig iron market are led by Southern iron, but all advances and declines in Southern iron are not followed by corresponding movements in the general market. There has been, however, some weakness in Northern markets. Chicago, influenced greatly by Southern iron, which is mixed with Northern in that territory, has shown signs of weakness though quotable prices are not lower. The Philadelphia market has seen some shading, though no general decline. In the Pittsburgh market steel making irons have been firm, but in foundry iron there has been the unprecedented incident of Cleveland iron being offered at 50 cents under the valley parity. This is novel rather than irrational, however, since it is a fact that, considering freights, Cleveland can afford to assemble raw material and deliver pig iron to Pittsburgh about 25 cents a ton cheaper than the valleys, which have controlled the Pittsburgh market from time immemorial. We quote: Bessemer, \$17.25; basic, \$16.50; No. 2 foundry, \$17.50; forge, \$17; malleable, \$17.25, all f.o.b. valley furnaces, 90 cents higher delivered Pittsburgh. No. 2X, delivered Philadelphia, \$18.50; No. 2 foundry, delivered Cleveland, \$17.75; No. 2 foundry, f.o.b. Chicago furnaces, \$18. No. 2 foundry, Birmingham, \$13.50 to \$14.

Steel

The famine in unfinished steel, referred to in previous reports has become if possible more pronounced. There is practically no steel available in the form of billets or sheet bars. Of course occasional lots appear, but they are the exception which tests the rule, having in mind particularly how quickly they are absorbed. Thus the receiver of the Southern Steel Company desired to dispose of 5000 tons a month of open-hearth billets over the first half, it being desirable on account of the financial position of the company to have the steel sold, and the material was all quickly taken, the United States Steel Corporation absorbing 15,000 tons for its Pencoyd plant, which should be supplied fully by the Carnegie Steel Company, while the balance was taken in small lots, chiefly by Eastern rolling mills. In Pittsburgh occasional small lots are sold. Ingots have become a market commodity, there being occasional excesses of melting capacity over blooming capacity at points, matched by occasional excesses of blooming over melting capacity at others. Prices cannot be quoted closely, because there is no definite market. In a general way it may be said that billets and sheet bars, if offered, would bring \$20 to \$30, f.o.b. maker's mill, Pittsburgh or Youngstown.

Finished Steel

Effective January 13, the American Sheet & Tin Plate Company advanced its prices \$2 a ton on all regular products except tin plate, and including blue annealed black sheets, tin mill black and galvanized sheets, carrying also corrugated roofing which are now sold on the basis of flat sheets plus extras. Many of the independents had already advanced their figures, and the advanced figures of the leading interest at once became the minimum of the market. Early in the month cold rolled shafting was advanced two points or \$2 a ton to 58 per cent off list in carload lots, delivered in base territory.

Regular prices for forward delivery are given below, plates, bars and sheets commanding a premium for almost any delivery before June, while small premiums rule on some other products. Prices are at Pittsburgh unless otherwise specified. Rails, standard sections, 1.25 cents for Bessemer 1.34 cents for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.50 cents

Shapes, 1.50 cents.

Steel bars, 1.40 cents.

Steel hoops, 1.50 cents

Common iron bars, 1.65 cents, Pittsburgh; 1.60 cents, Chicago; 1.67½ cents, Philadelphia.

Sheets, blue annealed, 10 gage, 1.75 cents; black, 28 gage, 2.35 cents; tin mill sizes of black, 28 gage, 2.30 cents; galvanized, 28 gage, 3.50 cents; painted corrugated, 28 gage, 2.55 cents; galvanized corrugated, 28 gage, 3.55 cents.

Tin plates, \$3.60 for 100-lb. cokes.

Merchant steel pipe, ¾ to 3-in., 80 per cent off list.

Steel boiler tubes, 3½ to 4½ in., 71 per cent off list.

Standard railroad spikes, 1.85 to 1.90 cents.

Button head structural rivets, 2.20 cents; cone head boiler rivets, 2.30 cents.

The Non-Ferrous Metal Market

There were no unusual features in the non-ferrous metal market in January. Sales of metal were rather below normal, and quoted prices were in many instances discounted in order to obtain business. Domestic consumers seem to buy only for immediate needs and from small agencies. More business was transacted in lead on account of the favorable price, but later in the month this market was dull also.

Copper.—The principal producers have not realized their quoted price. Only a small business in Lake copper is reported. Sales for future delivery have been made at about 17.40 cents, New York, and the market was generally dull. The last quotations are 17¼@17¾ cents for Lake and 17.35@17.45 cents for electrolytic.

Lead.—This market has shown a firm tone, but business disappeared when higher prices were asked. The St. Louis market quotes 4.15@4.20 cents, with New York at 4.30@4.35 cents.

Tin.—Early in January there was a slight premium on spot metal, but this later disappeared. Visible supplies at the end of the year were smaller by 5,500 tons than at the beginning of 1912, and it is expected that this will result in an upward movement in the London market. January tin was quoted at 50¾ cents, New York.

Spelter.—Not much business has been consummated in this market, especially for immediate delivery. Future deliveries are discounted considerably. The market is practically unchanged at the following prices: 7.05@7.10 cents, St. Louis, and 7.10@7.20 cents, New York.

Other Metals.—No material change is noted in aluminium, the last quotations being 26@26½ cents, New York. Sales of antimony have been light, prices ranging from 9 to 10¼ cents for various grades. Business in quicksilver has been light, and prices remain at \$40 per flask of 75 lb., New York and San Francisco.

A New Honor for Dr. Acheson

Dr. Edward Goodrich Acheson has been made an honorary member of the Imperial Technological Society of St. Petersburg, Russia, before which body he delivered an address on the evening of Jan. 20.

American Museum of Safety

On Jan. 23 the American Museum of Safety, 29 West Thirty-ninth Street, New York City, held its annual exercises for the award of its four gold medals.

The *Scientific American Medal* for the most efficient safety device invented during the last three years and exhibited at the Museum's exhibit hall was awarded to the *Dräger Oxygen Apparatus Company*.

The *Travelers' Insurance Company Medal* for the American employer who in the judgment of the American Museum of Safety has done the most for the protection of the lives and limbs of workmen was awarded to the *New York Edison Co.*

The *Louis Livingston Seaman Medal* for progress and achievement in the promotion of hygiene and sanitation and the mitigation of occupational disease was awarded to the *National Cash Register Company*.

The *Rathenau Medal*, placed at the disposal of the Museum by the Allgemeine Elektrizitäts Gesellschaft, for the best device or process in the electrical industry for safeguarding industrial life and health, was awarded to Mr. *Thomas Alva Edison*.

Atlantic City Meeting of the American Electrochemical Society

The Spring meeting of the American Electrochemical Society will be held at Atlantic City on April 3, 4 and 5. Headquarters will be at the Hotel Traymore. Members and guests are advised to secure their accommodations early.

No complete program of papers, social functions, and excursions has been arranged so far, but it has been fixed that there will be a symposium of papers relating to the electrolytic decomposition of metals and electroplating, the different metals to be taken up by different authors.

Dr. W. Lash Miller, of the University of Toronto, Ontario, Canada, is the president, and Dr. Jos. W. Richards, of Lehigh University, South Bethlehem, Pa., is the secretary of the Society.

Chemists' Club Library

The library of the Chemists' Club in New York is now getting into fine shape and is being used by a steadily increasing number of members and visitors.

As one fruitful source of criticism of libraries in general is ignorance of the method used by the particular library which is visited by the critic, the library committee has issued the following advice "how to use the library":

"Thanks to the kind co-operation of Dr. Billings, director of the Public Library, and Mrs. Smith, librarian of the Academy of Medicine, any book can be located exactly on the shelf by a system that will never obstruct unlimited expansion.

"To find a book (say, Lunge, Sulphuric Acid, etc.), look it up in the card index by either author, title or subject. Note the class mark (Acid) in the upper corner of the card. Refer to the chart on the card case and find the shelf mark for this class (F 3.5). Go to the stack labeled with this letter (F) on the side marked with the first figure (1-3) to the vertical row of this number counting from left to right (the third) and the shelf of the last number (5) counting from the top down.

"To find all books on a general subject: Look for your subject (or the division that includes it) on the chart, note the shelf number and proceed as above.

"When more than one shelf is occupied by a group, the books are in alphabetical order by authors' names.

"The library is open to the public from 9 a. m. to 5 p. m., except Saturday afternoons, Sundays and holidays; entrance through the public hall and elevators to the third floor."

The Petroleum Industry in 1912

There was no considerable change in the quantity of petroleum produced in the United States in 1912 compared with 1911. Nevertheless, according to David T. Day, of the United States Geological Survey, the year was as full of remarkable incidents as is usual in the history of this article of commerce, which depends for its statistical position more upon the chances of new discoveries and less upon trade demands than any other commodity except gold.

As a rule, the Eastern fields declined in production, because it was impossible to keep up the great output of 1911 without large additional discoveries of new pools in the older fields. The Eastern decline was, however, offset by the increase in California, where the San Joaquin Valley fields (Midway, McKittrick, Maricopa, etc.), are still at the height of the gusher stage.

The total production in the United States in 1912 was 220,200,000 barrels (of 42 gallons) against 220,449,391 barrels in 1911. The chief producers were California (87,000,000 barrels), Oklahoma (52,000,000 barrels), and Illinois (28,000,000 barrels).

Presentation of the Perkin Medal to James Gayley

The Dry Blast Process as One of the Greatest Achievements in Modern Metallurgical Chemistry

THE Perkin medal was awarded for the present year, to Dr. James Gayley. The medal is awarded annually to a chemist residing in America "for achievements of high value in applied chemistry." The award is made by the Perkin Medal Committee which is constituted of representatives of the different chemical societies of this country. The former recipients of the medal were: Sir William Perkin, Dr. J. B. Francis Harreshoff, Dr. Arno Behr, Dr. Edward G. Acheson, Dr. Chas. M. Hall, and Mr. Herman Frasch. The award to Dr. James Gayley was made in recognition of his dry-blast process as one of the greatest achievements in modern metallurgical chemistry.

The formal presentation of the Perkin medal to Mr. Gayley took place at the meeting of the Society of Chemical Industry held at the Chemists' Club in New York City on the evening of January 24.

Prof. M. C. Whitaker in calling the meeting to order emphasized the presence of so many captains of industry who had come to honor Mr. Gayley. He then introduced Dr. Chas F. Chandler, the senior vice-president of the Society of Chemical Industry who made the presentation speech.

In giving a sketch of Mr. Gayley's life Dr. Chandler mentioned that James Gayley is the maternal grand-nephew of Sir Henry Bell, who established steam navigation on the Clyde, where he launched "The Comet" in 1812. He was born at Lock Haven, Pa., October 11, 1855, the son of Samuel A. and Agnes (Malcolm) Gayley. The following brief statement of the successive stages of his professional life are significant:

"Mr. Gayley began his professional life as chemist for the Crane Iron Company, Catasauqua, Pa., 1877-80. He was next superintendent of the Missouri Furnace Company, St. Louis, and later was the manager of blast furnaces, E. & G. Brooke Company, Birdsboro, Pa., 1880-85. In 1885 he became manager of the blast furnaces at the Edgar Thomson Works, and he was subsequently promoted to the position of manager of the Edgar Thomson Works, and he later became a managing director of the Carnegie Steel Company. In 1907, he was made first vice-president of the U. S. Steel Corporation, remaining in this position until 1909."

Dr. Chandler emphasized the enormous importance of the dry air blast and in concluding he presented the Perkin medal to Dr. Gayley with the following words: "It gives me great pleasure, as the representative of the Society of Chemical Industry, and the affiliated chemical and electrochemical societies, to place in your hands this beautiful token of the appreciation and affection of your fellow chemists."

Dr. Gayley replied in a few graceful words of thanks, followed by a most interesting story of the evolution of the dry-blast process. His speech follows practically in full:

The Story of the Dry-Blast Process

By James Gayley

"I wish to thank the speaker for this medal which he has presented to me with such gracious words. I wish also to express my thanks to the awarding Committee and the Societies which they represent in conferring this great honor upon me. I appreciate it still more because the committee have stepped aside from what is purely the chemical industry to another great industry, that of iron metallurgy, which, nevertheless, is one in which the application of chemistry is the controlling factor, and this recognition of the broader field of chemistry brings

with it a keen sense of appreciation of this rare honor and distinction conferred upon me. Again I thank you.

"The iron blast furnace is but the chemist's crucible on a gigantic scale—operated on chemical principles and the mechanical appliances are instruments of precision, constructed and adjusted to carrying out in efficient manner the chemical reactions involved.

"The 'rule of thumb' practice, which ended thirty-five or forty years ago, is well nigh forgotten—that period in which chemistry was not applied, and a ton of ore was a ton of ore all the world over, irrespective of its reducibility or chemical composition; when the iron master was more interested in the output of 1.8 iron than in the fuel consumption, and would tell you that 'lime made heat.' David Thomas, that grand old pioneer of the anthracite iron industry, summed up the requisites for successful furnace practice as 'wind and heat.' The application of chemistry to iron smelting has effected a wonderful transformation in the industry, so that today the chemist occupies the foreground in directing its operations.

"Moisture in the atmosphere has long been recognized as a variable and influential element in the manufacture of iron. Truran, in his 'Manufacture of Iron,' written in 1802, refers at length to the influence of moisture on the quality and make of iron, and the increased consumption of fuel in the summer season, but does not touch on the problem of its regulation or removal.

"Later, in England, it was proposed to extract the moisture by passing the air over lumps of chloride of calcium, but Sir Lowthian Bell showed the impracticability of that scheme on account of the rapidly diminishing power of absorption possessed by the calcium chloride.

"Charles Cochran, an eminent iron manufacturer of Great Britain, proposed and obtained a patent on extracting moisture from the air by bringing it into intimate contact with liquid calcium chloride flowing over chains suspended in a chamber; but later he declared respecting the benefits to be derived from extracting moisture that 'the game was not worth the candle.'

JAMES GAYLEY

Nevertheless, the moisture in the atmosphere was recognized as a disturbing element. Some of the earlier makers of anthracite iron in the Lehigh Valley stated that they frequently knew in the morning what kind of iron their furnaces were making by observing the weather conditions; yet, prior to the first dry-air installation in 1904, this variable element of moisture was accepted in a spirit of resignation, as something to be endured, like storm and sunshine, a condition beyond control.

"It was my privilege to be invited in 1885 to take charge of the Edgar Thomson blast furnaces of the Carnegie Steel Company, a plant which represented the most advanced construction in blast furnace equipment, and was supplied with the best fuel and ores. In the operation of these large furnaces, the influence of the atmosphere was forcibly impressed, as the steel works were being supplied with hot metal direct from the furnaces, for the Jones metal mixer had not come into use. It was a difficult matter to supply metal approximating uniformity even under the best conditions, and quite impossible under conditions of varying atmospheric humidity.

"For several years observations were made twice a day of the moisture in the atmosphere, and a direct relation was established between the quantity of moisture and the grade of metal, with particular reference to the silicon which is the heat-producing element in the acid Bessemer converter. In the summer season, the air blown into the converter was heavily charged with moisture and, in consequence, a higher percentage of silicon in the metal was normally required, while at the same time these atmospheric conditions operated on the furnaces to produce a lower-silicon metal; thus the operating of furnaces in conjunction with Bessemer converters on direct metal may well be presumed to have been a difficult and trying proposition.

"Under these conditions of manufacturing, the removal of the moisture from the atmosphere, or rather its reduction to a low degree, and one of practical uniformity, appeared to hold out the only means of effecting regularity, and at the same time to promise a considerable saving. It was a matter of constant observation that a sudden change in the weather, making a quick drop in the temperature and content of moisture, would cause the furnaces to work excessively hot, but this period of dryness could not be taken advantage of, for before any changes could be made effective in the furnace charge to meet current atmospheric conditions the moisture might have increased to its normal seasonable amount.

"Observations of the humidity in the atmosphere were made daily from 1886 to 1890, when the first experiments for moisture removal were begun. These observations were made at the beginning in the morning and evening, and later were made every hour. Observation was also made of rainstorms to determine the moisture before, during and after the rain, and it was noted that the moisture usually dropped quickly as the rain began to fall. Throughout this period of moisture tests, the working of the furnace was observed in its relation to the amount of moisture in the atmosphere.

"A modern furnace consumes about 40,000 cu. ft. of air per minute, and for each grain of moisture per cubic foot there enters the furnace 1 gal. of water per hour for each 1000 cu. ft. that is, if the moisture was 1 gr. per cu. ft. 40 gal. of water would enter the furnace per hour. The variation of moisture from month to month in the Pittsburgh district is shown in the following table:

	Average Temperature Degrees Fahrenheit	Weight of Water Per Cubic Foot of Air Grains	Quantity of Water Entering Per Hour Into a Furnace Using 40,000 Cubic Feet of Air Per Minute Gallons.
January	32.6	3.18	87.2
February	31.7	1.83	73.2
March	45.0	3.40	136.0
April	51.0	3.60	120.0
May	61.6	4.80	162.0
June	71.6	5.03	237.6
July	76.2	5.60	224.0
August	71.6	5.16	206.1
September	70.4	5.68	227.2
October	56.4	4.00	160.0
November	40.4	3.35	94.0
December	36.6	2.25	90.0

While the moisture in January averaged 2.18 gr., yet the total variation for the month was from 0.36 gr. to 2.55 gr., and while June shows an average of 5.94 gr., yet the extreme variation was from 4.8 gr. to 8.50 gr., or, in other words, the moisture entering the furnace varied from 192 to 340 gal. per hour. During the midwinter period the moisture may vary as much as 150 per cent in the same day, but in midsummer it rarely varies more than 25 per cent.

"Having secured extensive data on the varying humidity of the atmosphere over a period of five years, the problem of reducing the moisture and making it uniform next presented itself.

"The experience of English engineers was against the absorption process with calcium chloride, and my predecessor at the Edgar Thomson Works, Mr. J. H. Cremer, had constructed an apparatus to dessicate in the same way, but he obtained very unsatisfactory results. As our observations showed a reduction of moisture through a reduction of atmospheric temperature, the reduction of temperature through mechanical refrigerators presented itself as the obvious method of removing the moisture; and on this basis the first experiment was undertaken in 1890 in a crude way.

"We began by passing air through two chambers in succession; in the first chamber the air came in contact with pipes cooled by water, and in the second chamber anhydrous ammonia was expanded through the pipes. As the air came from the blowing engine it was quite warm, but after passing through the chambers it was very cold; each chamber was only 6 ft. long and the volume of air treated was small, indeed.

"Various forms of apparatus were constructed from the period of 1890 to 1895, and tests were made as opportunity offered. During this period my duties had been changed from that of superintendent of the furnaces to general superintendent of the whole works, thus adding to my duties that of the steel works and mills. There was in consequence not much time free to make experiments, for the demands of a large steel works on its manager's time were persistent and exacting, and experiments and improvements along other well-defined lines represented more immediate profit and demanded thought and attention. But the general plan for a final test on a large scale had been worked out, which was to be tried later. In 1896, I left the active management of the works to enter upon the general business of the Carnegie Steel Company in connection with the ore department and the assembling of all raw materials. If the opportunities for experimenting were rare when stationed at the works, they became more so when located in the general office.

"I therefore secured the services of a young engineer, Mr. Walter, from a refrigerating company, and when they learned the nature of my experiments they kindly loaned me a small ammonia compressor to carry on the work. We used two air-drying chambers, each 4 ft. square and 8 ft. long, and filled with pipe coils, and equipped with the necessary refrigerating appliances. A blast engine with an air cylinder, 3 ft. in diameter and capable of supplying 3500 cu. ft. of air per minute was installed, and from this engine and its small air supply the data was worked out for treating 40,000 cu. ft. of air, which was the quantity required to supply a modern blast furnace.

"I mention that we had to work out the necessary data for a practical demonstration, and the suggestion might arise, why did we not avail ourselves of the experience of refrigerating firms? Indeed, we tried. The proposition was put up to several important makers of refrigerating machinery, but without any substantial benefit. To refrigerate the air for cold storage rooms was a specification they readily understood, but the treatment of a hurricane of air was an entirely different problem to them. We were, therefore, compelled to work out the data ourselves and make our own card of estimate.

"It is unnecessary to give in detail the many and varied experiments made in treating the air, nor to describe how certain obstacles, which seemed to block our progress, were successfully overcome. In our list of experiments we tried rarefac-

tion with refrigeration, but we did not obtain satisfactory results.

"For quite a period the chamber into which the cold air was discharged accumulated a large quantity of snow, and the air flowing in produced a veritable snowstorm. This was delightful on a hot July day, but unless we could overcome this snowstorm it would be disastrous to the process, for the snow would soon become aqueous vapor. We tried to extract it from the air, but without success.

"The essential thing was not to produce it, and in this we were finally successful. We were trying to refrigerate to a very low and unnecessary degree and the frost did not become fixed on the cold pipes; by increasing the temperature of the brine circulating through the pipes the snow became fixed and promptly disappeared from the cold air blast. We worked generally under conditions of the highest humidity in the Pittsburgh district, which we secured by admitting steam to the air inlet when necessary.

"About the year 1900 we had plans worked out in detail for a plant to treat 40,000 cu. ft. of air per minute, and I then applied to my company for an appropriation of \$100,000 to make this installation, and here my most difficult work began—to persuade my associates that moisture in the air could appreciably, even in a small degree, affect the working of a blast furnace.

"It could hardly be expected that men who came up through the ranks of the steel works or office should appreciate the influence of atmospheric changes on a blast furnace that to all external appearances was crude and rough, but which in its interior adjustment was really on a most delicate balance. Money was readily appropriated for the mechanical appliances of the furnaces, or for securing uniformity in the physical and chemical composition of the ores, coke, and limestone, and a variation therein of 10 per cent to 20 per cent was promptly corrected, but the atmosphere might vary from 20 per cent to 150 per cent even in a single day without giving any concern, for few realized that the weight of air consumed per ton of iron was 50 per cent greater than all the other raw materials combined.

"It was not until 1903 that I secured an appropriation to construct the first plant, although I had offered two years before to assume personally half the expense.

"Early in June, 1904, the dry-air plant, which was erected at the Isabella furnaces at Pittsburgh, was in proper working order and ready to be put on the furnace. It was necessary to apply the dry air gradually so as not to disturb the furnace adjustment, and as there were three blast engines we arranged to first supply dry air from one engine, making the blast one-third dry air. We decided to apply this dry air at 9 a. m. and I had the weight of ore charge increased by 5 per cent, and this increase was timed to reach the combustion zone of the furnace at 11 a. m. The furnace manager protested against the addition of 5 per cent, contending that a 2 per cent increase was about the limit, and if the dry air did not prove efficient he would then have a very cold furnace on his hands. Notwithstanding the objection, the increase was made. When the dry air was turned on at 9 a. m. the furnace soon showed the effect of it, the gas became grayer, a sure sign of the furnace working hotter, and when the 5 per cent increase in ore had reached the hearth it was not discernible that the furnace had been given an increased duty.

"The operations of the furnace were conducted on a conservative basis, and the long time spent in working out and developing the air-drying plant was rewarded, for the plant started and continued to perform its work without a hitch. By the sixth day the furnace was being supplied with two-thirds dry air and one-third natural air, and 9 per cent increase in ore charge had come to work; and the furnace condition was splendid. I might add here that the 9 per cent increased weight of ore charge represented the same percentage increase in output and a like reduction in the amount of fuel used per ton of iron.

"On the afternoon of that sixth day in the use of dry air

I left the works well satisfied with the progress made and confident of the future by reason of the many little indications easily recognized by practical furnacemen that a still heavier duty would be responded to.

"I had not gone far when the sound of an explosion reached me, and, on turning, I saw great clouds of steam rising from the works. I hastened back, and feeling my way through steam and dust, I was dismayed to find that the refrigerating chamber had collapsed.

"There it lay, a tangled mass of concrete and distorted pipe coils.

"The building gave way because during a part of the time employed in erecting the dry-air plant there was a bricklayers strike and the works manager not wishing to delay construction built the refrigerating chamber of concrete. The dry-air blast conduit leading from the top of the chamber to the blast engines was constantly vibrating from the impulse of air and the vibrations of the engines. These vibrations were in turn communicated to the dome of the building, weakening the base of the concrete and caused the walls to collapse, which in their fall broke the steam pipe leading to the compressors. The debris was cleared away, and in less than two months the plant was again started.

"We began as before and in two weeks' time had secured a fuel economy of 15 per cent, and then by small increments we gradually worked up to a point of 20 per cent efficiency. That is, we effected a fuel saving of 20 per cent and increased the output to the same extent. This practice was continued for about six months, but the manager thought it was operating too close to the danger line to take care of irregularities in the raw materials, and the fuel economy was adjusted to 15 per cent. Even with dry-air blast there is a disinclination to work up to the high limit of efficiency, for the prior experience of every furnace manager with natural air had shown the necessity of keeping a good margin of safety."

Mr. Gayley then exhibited two models of apparatus for drying air. In the first model, which represented his first installation, there is a chamber filled with pipes and the air is cooled by indirect contact with a cooling fluid, which is brine. The temperature of the brine is such that the air entering the chamber at 80 deg. is discharged at 23 deg.

The second model represented the two-stage process in which the air is brought into direct contact with refrigerated water in the first chamber and is reduced to about 35 deg. in temperature, then it passes to the second chamber filled with pipe coils through which brine circulates and the final temperature is obtained. The two-stage method is more cheaply operated and costs one-third less to build.

"It was not our purpose throughout our experiments to work out the most economical method of drying air for the first installation. What we aimed at was to construct a plant that would efficiently and continuously produce dry air in order to determine its economical value in the furnace."

Mr. Gayley then showed a chart which illustrated the variability of moisture in natural air and the regularity of dry air. During the thirty-one days of July, 1910, the moisture in the natural air averaged between 31 and 8.22 per cubic foot of air, while the moisture in the dried air of the dry-blast process was uniformly equal to 0.822 of moisture per cubic foot of air. In other words, with dry blast 800 gal. of water were delivered to the blast furnace every twenty-four hours, while with natural air the amount of water delivered would have averaged between 3400 and 7800 gal. per twenty-four hours.

"The records obtained at several works from the use of dry air, and which in each case cover a considerable period are as follows:

"Works A—Obtained a decrease on coke consumption of 10.5 per cent and an increase in output of 23 per cent.

"Works B—Obtained a decrease in coke consumption of 6 per cent and an increase in output of 15.3 per cent.

"Works C—Obtained a decrease in coke consumption of 9.8 per cent and an increase in output of 11.8 per cent.

"Works D—Obtained a decrease in coke consumption of 10.5 per cent and an increase in output of 16 per cent.

"The results obtained at different plants are modified by the raw material used, and the personal equation of the management enters into it.

"The results given above are taken from works in three different countries. *The claim I personally make for the process is that with an increase in output of 10 per cent the saving in fuel per ton of iron will be reduced 10 per cent, and I consider this conservative.*

"One of the advantages obtained through dry air is the elasticity it permits in the furnace operations to meet business conditions. If trade is dull the furnace can be operated to secure the maximum of fuel economy with a small increase in output, but when trade is 'booming' and pig iron is in demand, and increased output is more desirable than a saving in fuel, the furnace can readily be made to respond.

"The manager of the Dowlais Works, at Cardiff, Wales, experimented with one furnace to determine what results could be obtained under each condition of operating.

"For a period the furnace was operated principally to secure increased output and obtained an increase of 26 per cent with a fuel saving of 12.3 per cent.

"In the next period they operated principally to obtain decreased fuel consumption and obtained an increase in output of 12 per cent with a decrease in fuel of 17.4 per cent.

"In addition to the advantages from dry air already mentioned, it is found that the furnace works with greater regularity and in consequence a more uniform metal is produced, and a required grade of metal can be made with precision.

"In low-silicon irons the sulphur does not increase as it does when natural air is used.

"The saving in coke effects a corresponding saving in the limestone necessary to flux the ash of the coke, and there is less phosphorus entering the metal.

"As the furnace charges settle more regularly, there is less fine ore carried over with the gases.

"A manager of blast furnaces using dry air recently said that they found it to be an 'educator' in their practice, as it had taught them the advantage of securing regularity in many other directions.

"I shall not attempt herein to set forth any of the theories advanced to account for the fuel saving, which has been found to be in excess of what is necessary to dissociate the moisture. That feature has been ably discussed by Dr. Henry M. Howe, Prof. J. W. Richards, Mr. J. E. Johnson, Jr., and many others in this country, and also by metallurgists in England, Germany, and France; and their full discussions can be found in the transactions of the American Institute of Mining Engineers, the *Journal of the British Iron and Steel Institute*, and metallurgical journals.

"Towards a full consideration of the dry-air blast, a few points may be referred to briefly:

"It did not come into its work as did the Neilson hot blast in 1828 when the art was crude and the appliances of the furnace were poorly adapted to the work. But to the Scotchman Neilson all credit is due for effecting a fuel saving of 30 per cent.

"The dry-air blast was tried out when the equipment of the furnace was as perfect as human skill could make it. The chemistry of furnace operations was well understood and its management was on a skillful and scientific basis.

"Again, it was not possible for dry-air blast to have an experimental stage. Nearly every device or process can be tested in an experimental way and on a comparatively inexpensive scale. Bessemer could blow air through molten metal in a pot and demonstrate the value of the pneumatic process, but it would have been of no value to build a small plant to refrigerate a part of the air, nothing conclusive would have been shown. Nor would it have been of any value to treat the whole air supply of a diminutive or toy furnace. To efficiently demonstrate its value it had to be applied to a furnace that was equipped and operated according to the most ad-

vanced state of the art, and not only was it essential that the whole air supply should be treated, but also that the method and means of treatment should measure up in capacity and efficiency and operate as continuously as any of the other accessories of a modern blast furnace. To achieve this it required time, patience, and many experiments, and now with its accomplishment, in removing irregularity from the most important and invariable factor in the winning of iron from its ores, it apparently removes the last barrier toward the attainment of ultimate economy in the present field of practice.

"This, in brief, is the story of the dry-air blast."

Addresses by Prof. Howe, Dr. Hart and Dr. Raymond.

Prof. **Henry M. Howe**, of Columbia University, followed with a brilliant address on the metallurgy of the dry-blast process, spiced with sarcasms on the light which the development of the dry-blast process has thrown on the value of expert opinion.

A saving of fuel of 20 per cent or 10 per cent had been considered as preposterous, as absolutely impossible. But then it became a fact. "Let us learn the lesson of humility." Now as the heat required for heating and dissociation of the moisture is so very small, how can the big saving in fuel, due to dry blast, be explained? Dr. Howe emphasized the supreme importance of temperature. There is a critical temperature in the blast furnace reaction and accordingly there is hypercritical and hypocritical heat and hypercritical and hypocritical work, and any change of the ratio of hypercritical to hypocritical heat has its effect.

We hope to publish Professor Howe's address in a future issue.

Prof. **Edward Hart**, of Lafayette College, followed with an address on "Dr. Gayley's Interest in Education." Professor Hart told of what Dr. Gayley has done for various institutions of learning in this country. His speech was delightful, as he told of many humorous and intimate reminiscences from Mr. Gayley's early life. While Professor Hart was Mr. Gayley's teacher in chemistry, yet he emphasized that Mr. Gayley had always been highly original and was in many ways a self-educated man. One of Mr. Gayley's chief traits of character was his consideration for other people's feelings.

The session was concluded by an eloquent and highly poetical speech by Dr. **Rossiter W. Raymond** on the present time as a "new age."

Old Freibergers in America.

On Friday evening, Dec. 20, at the Hofbrau-Haus, Broadway and Thirtieth Street, New York City, a number of old students of the Freiberg Bergakademie sat down to dinner. This meeting was called for the purpose of forming an association in America to be known as the "Old Freibergers in America."

After the dinner a business meeting was held and the following officers were elected: President, R. W. Raymond, Freiberg, 1861; vice-president, Gardner F. Williams, Freiberg, 1868, and secretary-treasurer, C. L. Bryden, Freiberg, 1907.

It was decided to hold two meetings a year, one on March 25, the anniversary of the founding of the Akademie, March 25, 1765, and the other on Dec. 20, this to be the annual meeting.

The following members were present: Dr. R. W. Raymond, 1861; Gardner F. Williams, 1868; P. J. Oettinger, 1867; Stuart M. Buck, 1868; T. Waln Morgan Draper, 1876; Baron Alfred von der Ropp, 1882; Franklin Guiterman, 1877; F. G. Corning, 1879; R. Boice, 1908; Albert Meyer, 1908; R. M. Payne, 1909; Dr. E. E. Lungwitz, 1886; F. H. Sistersmans, 1885; George M. M. Godly, 1900; Walter V. Rohlfis, 1903; H. H. Knox, 1886; H. A. Wilkens, 1880, and C. L. Bryden, 1907.

All old Freibergers who have not already done so are requested to send in their names and addresses to the secretary, C. L. Bryden, 1015 Myrtle Street, Scranton, Pa.

Utilization of Waste Wood

Raw Materials

By John E. Teeple, Ph.D.

For the purposes of this article we will include under the term "Raw Materials of Wood Waste," saw dust, ends, slabs and edgings from lumber mills, stumps from lumbering operations, and fallen or dead timber in the woods, caused by storms, and not suitable for lumber. We do not include the tops and branches of trees cut for lumber and left in the woods, because no suitable method has yet been worked out for rendering them commercially valuable, and we do not include young trees, particularly of short-leaf pine such as are used for making paper pulp to some extent, because it is permitted to grow they would eventually be suitable for lumber.

In kind, waste wood may be the long-leaf pine of the South Atlantic and Gulf States; short-leaf pine of the same general region, and various other pines intermediate between them in characteristics: Oregon pine or Douglas Fir of Oregon, Washington and British Columbia; Norway or red pine of Ontario, Manitoba, Minnesota, Wisconsin and Michigan; and hardwood of many parts of the United States and Canada.

This gives us at least four forms, viz., saw dust, slabs, stumps and fallen timber, and at least five classes of wood.

It is obvious that the recovery of valuable materials from short-leaf pine, saw dust for example, is an entirely different problem from that presented by long-leaf pine stumps, which is again different from the treatment of hardwood slabs. In fact, this simple classification into four forms and five kinds of wood presents of itself twenty distinct problems.

The situation is further complicated by differences in each class; long-leaf pine stumps for example differ widely in composition, depending on age, soil, elevation of the land, latitude, and probably on the season of the year when the tree was cut.

When any proposition for utilizing wood waste is presented then, the question of form and kind of raw material and location becomes exceedingly important. The only safe assumption is that conditions in any one place are not identical with those in any other place. The individual problems presented are practically as numerous as the individual locations and conditions. These differences must be taken into account and studied carefully before any specific plant can be designed, or any particular process recommended intelligently for the case in hand.

Given a general class of conditions, one can outline a general plan of plant, or predict the probable success or failure of a general idea when applied to those conditions. He cannot go much farther than this without a careful examination of the specific raw material and location. Too often success or failure depends on specific adaptation to individual local details, and not on general ideas applied to general conditions. This is especially true in this industry, dealing as it does with bulky materials not easily transported, not permitting much in the way of handling charges, yielding comparatively small amounts of products and those products not universally salable, often none of them salable within hundreds of miles of the point of production.

We cannot then give too close attention to raw materials, and it may be necessary or advisable in a particular case to reject one-half or nine-tenths of the waste offered in order to work successfully with the remainder.

No matter what form or kind of wood is presented within the limit specified above, we may for our purpose consider it to be composed of three parts: First, water; second, structural frame work, and third, gum resins. The first part, water, may form anywhere from 25% to 50% of the weight of the wood. It is often given a high value in the prospectus, but the demand for it seems to be rather light. The second constituent, the structural part of the wood, consists essentially of cellulose, various lignocelluloses, and similar products chiefly carbohydrates. This makes up the wood itself. It is the frame work, the part that gives it texture. It is, of course,

present in all woods, and, in many of them, particularly in the hardwoods, there is no other important constituent present excepting this cellulose framework and the water. The third constituent of the wood is resin or gum resin. This affects the color and weight of the wood, and is a deposit in the interstices of the woody framework.

When extracted from wood, the gum resins may be easily separated into turpentine, pine oil, and rosin. In pine woods, the first or volatile part of the resin is turpentine, or a mixture of terpenes, the kind and quantity of the different terpenes varying in different species of pine. The second part, still volatile but boiling at a somewhat higher temperature than the turpentine is pine oil. It consists essentially of hydrolytic and oxydation products of the terpenes. Most of the pine oil constituents contain oxygen. The third part of the gum resin deposit is rosin. This is the solid part not easily volatile with steam. Rosin is a mixture of different resins in different species of pine. The gum resins were the first products that led to the utilization of pine wood for uses other than lumber, and they still give the main value to waste wood. Considering the importance of the gum resins, it might be well to devote some attention to their origin and formation if we had any definite information about them.

If we make an incision into the pine tree it will nearly always produce a flow of sap or oleoresin or gum resin of a semi-liquid character, consisting of terpenes and rosin, no appreciable amount of pine oil. At the same time there is an increased deposit of gum resins in the body of the tree itself in the neighborhood of the wound. It seems probable that the oleoresin flowing from the tree is a combination of the natural sap of the tree and of another secretion formed to protect and reinforce the tree in the neighborhood of the wound. In case this wounding or chipping is continued from year to year, as is done in tapping trees for turpentine, the amount of deposit in the tree in the neighborhood of the wounded part becomes very large. The wood becomes so pitchy, or fat, that the butt of the tree is not suitable for lumber, particularly on the outside, and we have box faces or fat slabs which form a part of the waste of mills cutting long-leaf pine that has been chipped for turpentine.

When a long-leaf pine tree is cut in the woods, leaving a stump, the same process seems to go on in the stump. The sap wood gradually rots away, and the heart of the stump becomes richer and richer in gum resins as the years pass, producing finally what are known as fat light-wood stumps. This same thing occurs when a tree is blown down by storms, or if it dies standing, particularly where it has previously been tapped for turpentine. In some cases the stump becomes rich in gum resins down below the surface of the ground throughout most of the length of the tap root. In other cases there is no appreciable deposit of gum resin below the level of the ground. In the case of Douglas fir the deposits of gum resin are mainly in pockets produced by wind shakes, instead of throughout the framework of the tree itself, and this makes the yield of gum resin from that species very much more irregular than is the case with the long-leaf pine.

The fact that pine oils are important constituents of the gum resins extracted from old wood while they are scarcely present in the oleoresins obtained from the live tree by chipping it is probably due to slow processes of oxydation and hydrolysis going on in the stump or wood in the forest.

In the matter of cost: Waste from mills can usually be had at an exceedingly low figure, sometimes for nothing. The amount of waste usually considerably exceeds the amount required for fuel, and it often becomes a source of expense to take care of the remainder. The privilege of collecting fat light wood in the woods may usually be obtained at a cost of 10c to 25c per cord. Stumps can ordinarily be obtained for nothing, and if they are to be pulled out or cut off far enough below the ground so as to make the land tilable, the owner is often willing to pay \$8.00 or even \$12.00 per acre to have them removed.

The utilizable constituents of wood waste then are essentially the framework, which we call the celluloses for briefness, and the gum resins. The latter can be separated easily into turpentine, pine oil, and rosin. These are the only products existing in the wood in commercial quantities, or obtainable from it without using temperatures high enough to effect decomposition of the celluloses, rosin or oils.

The hardwoods contain no appreciable amount of gum resins, so the products derivable from them are, roughly speaking, only the products that could be derived from any other type of cellulose, for example they may be distilled to produce acetic acid, wood alcohol, tar and charcoal; they may be treated with alkali for conversion into oxalic acid; they may be treated with sulphuric acid for conversion into ethol alcohol. Some of them may be treated with soda, sulphite or sulphate for conversion into paper pulp. The yields in any or all of these cases, of course, will vary widely, depending on the nature of the hardwood.

The short-leaf pine contains a very small amount of gum resins, and also ordinarily contains more water than the hardwoods. The gum resins being in small amount are a disadvantage, because they contaminate the other products, and the yields both in quantity and in quality are liable to be inferior to those obtained from hardwoods, under similar conditions. So far as I know short-leaf pine waste is not being utilized at the present time, excepting for the production of ethol alcohol and paper pulp.

Long-leaf pine, Douglas fir and Norway pine may be classified together in this general way: If they are poor in resinous materials, then they can only be treated for the products obtainable from hardwood, and the products are liable to be inferior in quantity and quality, as stated under short-leaf pine. On the other hand, if they are rich in resins, this gum resin may be extracted direct and converted into any of the forms into which rosin, pine oil, and the terpenes are convertible, or the whole mass of wood may be treated together by distillation or otherwise, in which case we get various mixtures of products similar to those obtainable from hardwoods, with other products obtainable from the resins. This last method, unfortunately, has been the one most commonly adopted in the past, with the result that products of wood distillation too often have a reputation for indefinite and varying composition. In most cases it would be just as easy to separate the gum resins from the celluloses beforehand and to convert these separately into definite, uniform, marketable goods.

No account has been taken in this article of the mineral constituents of wood, nor of the various extracts which may be obtained from certain woods, like the oak and chestnut. The recovery of mineral constituents is not liable to become a factor in the near future, and extracts are not ordinarily produced from materials that would generally be classed as "waste wood."

The chief intent of this article has been to call attention to the wide variation of character in raw material presented, and the necessity of applying in each case the type of treatment which will be specially adapted to the character of the raw material.

New York City

The 1913 calendar of the **Brown Instrument Company**, of Philadelphia, Pa., shows a picture of the U. S. S. *Wyoming*, largest warship in the world, making 21 knots on her trial trip. There are Brown pyrometers used on the *Wyoming* for indicating the stack temperatures.

Mr. William E. Hartman, consulting engineer and expert in the construction of gas ovens and coke ovens, has been retained by the Gas Machinery Company, Cleveland, Ohio, with its oven department. Mr. Hartman was formerly associated with the H. Koppers Company, of Chicago, first as gas engineer in the construction of by-product coke ovens, and lately as managing engineer. A very interesting paper by Mr. Hartman on by-product coke ovens in America was published in our Vol. X, p. 521.

Sewage Purification

A Description of the Chemproco Sewage Disposal System

By James Millar Neil

Among sanitary engineers it is generally conceded that sewage consists practically of a mixture of 998 parts of water, one part of mineral matter and one part of organic matter, also that when reference is made to sewage purification, the same refers solely to this 1/10 per cent of organic matter which also includes the germ life.

Unfortunately, heretofore, no method in actual commercial operation eliminates completely all of this 1/10 per cent of organic matter contained in sewage, the difficulties encountered being the elimination of the soluble organic compounds and separation of the colloids from the treated sewage.

An ideal sewage purification process should possess the following advantages: The operating costs must be low; the plant required must have a low initial cost; the space required for the installation must be small; any reagents used must be low in cost; the resultant sludge must be easy of disposal; the effluent must be clear and harmless; the method of separating the solids from the liquid must be rapid and effective; under certain conditions the excess reagents in the sludge must be easily and cheaply recovered for use; the treatment operation and final products must be odorless.

The great defect in all present methods of sewage purification is that of filtration, and it is surprising to find how little ingenuity has been brought forward in solving this problem—every attempt at solution has been in the direction of sand filters, etc., with the corresponding technical difficulties pertaining to their satisfactory working and the enormous area of land required.

Sewage today can, however, be rapidly or, in fact, instantaneously purified, meaning thereby the complete separation of all of the solid matter contained therein, precipitation and separation of the organic matter, and the discharging of an effluent clear, odorless, and harmless. This result is obtained partially through the combination and application of the well known Moore suction filter, and a novel method of precipitation and separation of the organic and solid matters contained in sewage.

The operation of the process requires the use of suction pumps and vacuum filters, whose surfaces are permeable to liquids and impermeable to solids. The type of vacuum filter preferably employed is what is known in the arts as the Moore movable suction filter, as it allows of the separated solids being easily removed from the sewage treatment tanks at will.

By means of this process it will be found that not only are all of the conditions fulfilled for an ideal sewage purification process, but that its operation is simplicity itself.

The process consists essentially of the following steps or stages:

1st. The passage of the crude sewage through a screen or screens in order to remove the floatage and other large bodies contained therein.

2nd. Aeration in order to supply the amount of oxygen requisite for the complete precipitation of the organic matter and at the same time to maintain the contents of the sewage treatment tank in a state of agitation and thereby break up and granulate the solids, also for the purpose of commingling the precipitable and fatty matters with the precipitant so as to render them in a condition suitable to collection on the filtering medium employed.

3rd. Treatment of the sewage preferably while in a state of agitation by the requisite precipitating chemical reagents.

4th. Separation of the liquid from the solid matter in suspension in the treated sewage by means of filtration, instantaneously affecting the precipitation of the unprecipitated organic matter which heretofore has not been accomplished by any sewage purification process.

5th. Discharging of a clear, odorless and harmless effluent.

6th. Discharging a cake containing the impurities of the sewage and also containing the excess of chemical reagents used in the process.

7th. Recovery of the chemical reagents from the discharged cake for reuse in the process.

Before describing the individual steps or stages as they occur, a brief outline of what is meant by a Moore suction filter will facilitate the understanding of the operation of the process.

Fig. 1 is an illustration of a Moore filter leaf, which consists of a rectangular frame of tubing, enclosed by sheets of filter cloth suspended vertically from a rigid bar or header, the end sections or side tubes of the filter frame and canvas extending through the bar or header as shown in the illustration. The side tubes of the frame have no perforations, whereas the bottom pipe is usually slotted or channeled.

The filter cloths or canvas are reinforced by means of rows of stitches and stiffening or separating strips preferably of wood, which maintains the rigidity of the canvas or filtering medium when either pressure or vacuum is applied. As shown in the illustration, one of the side tubes is connected to a main

FIG. 1.—MOORE SUCTION FILTER LEAF

pipe or vacuum header connected by means of a flexible tube to the suction end of the vacuum pump. These leaves are made in any desired size, according to the filtering area required. This form of filter leaf gives an enormous filtering area, occupying very little space.

These filtering leaves are usually in practice coupled up in any desired number, and as such are known as a "basket." Fig. 2 illustrates a basket ready for use.

Fig. 3 illustrates a basket of leaves in place in a treatment tank, and a basket suspended out of the treatment tank by means of a traveling crane.

Fig. 4 is a side view of a complete sewage treatment plant, and shows the different steps of the process as set forth in the following description:

The operation of a Moore filter leaf is extremely simple. When the vacuum or suction is applied, clear liquid is drawn through the filtering cloths or canvas, depositing on the surface the solid matter in suspension in a cake of uniform thickness. The clear liquid in passing through the filtering medium is drawn through the slotted or channeled bottom pipe, thence through the side tube or pipe to the header, to the suction or vacuum pump.

In the operation of sewage purification, the initial step is that of preparing the chemical reagents used in the treatment tank, which is done by adding sufficient milk of lime until the tank contains an excess of lime, for example: 100 grains calcium oxide per gallon has been found to give excellent working results, and under certain conditions it may be advantageous to add other reagents such as calcium carbonate, sand, etc., as such reagents sometimes accelerate and improve the rate of filtration. In certain cases the addition of metallic oxides and hydrates also are found to greatly aid in the precipitation in the treatment of sewage from industrial plants.

The process of screening the sewage does not require any special or detailed description in this paper, as full details and data regarding the numerous types or methods at present in use can be obtained by reference to any standard treatise on sewage disposal.

The sewage to be treated is directed into the treatment tank, first passing through any approved system of screening in order

FIG. 2.—FILTER BASKET

to remove the floatage and other large bodies. The sewage on entering the treatment tank is agitated (and maintained in a state of agitation) for the reason explained, and into the treatment tank is introduced the requisite number of "baskets" of filter leaves which are submerged. Suction is then applied to the filtering mediums, whereupon a continuous flow of the agitated mixture is drawn toward the outer surfaces of the filter leaves, and on which the excess precipitant is deposited combined with the other solids in suspension. The liquid is then drawn through the film or cake of precipitant, thence through the filtering medium to the pump discharge.

By employing an excess of precipitant in the treatment tank, a film, layer or cake of the precipitant is instantaneously formed on the surface of the filtering medium, and it is found that the organic matter which heretofore it has been impossible to

FIG. 3.—BASKET OF LEAVES IN PLACE IN TREATMENT-TANK

precipitate is thereby precipitated, and retained and combined with the other solid matter in the sewage adhering to the outer surface of the filtering medium. In practice it is found that even though this excess is present, the actual consumption of the precipitant is not greater than the amount actually required to effect the complete precipitation of the organic matter contained in the original sewage. In this simple manner the

complete precipitation of the foreign matter is effected instantaneously, resulting in the continuous discharge of a clear and harmless effluent.

The filtering operation may be continued until the deposit of solids on the surface of the filtering medium becomes so thick as to unduly interfere with the volume of liquid being drawn through, which will be indicated by the vacuum gauge and discharge from the suction pump, in which case the filtering medium or "basket" may then be raised from the treatment tank by means of the traveling overhead crane and moved to the dumping point; suction being maintained in order to hold the cake of solids on the surface of the filtering medium during this removal step. If it is desired to reduce the moisture in the solids, the "basket" may be held suspended in the air under suction before dumping.

In order to remove the cake of solids from the surface of

the accumulated solids from the treatment tank, which latter may be done in the manner already described.

If at any time during the treatment of the sewage the effluent shows any trace of organic matter, this can be at once remedied by adding fresh precipitant to the treatment tank.

Owing to there being a continuous flow of sewage into the treatment tank, which in some cases carries valuable ingredients, this latter method of operation results in the accumulation of these ingredients in a fairly concentrated and desirable condition for subsequent treatment, whereby if desired, the oils, greases, etc., can be economically recovered, and the residue used as a filler for fertilizer.

A special feature of this method of sewage purification is the destruction of harmful bacteria without the aid of any germicide. However, in exceptional cases hypochlorite will effect the complete destruction of all harmful bacteria; it is

FIG. 4.—ARRANGEMENT OF FILTER PLANT FOR SEWAGE TREATMENT

the filtering medium, the suction is stopped and the cake is discharged therefrom by applying pressure by means of air or water within the filtering medium. After dumping or discharging the cake, the filtering medium of "basket" may then be immediately returned to the sewage treatment tank, and the filtering operation carried on indefinitely as already described.

Instead of raising and moving the filtering medium whenever it becomes coated the suction may be momentarily stopped, pressure applied and the solid matter thrown back or discharged into the treatment tank, and there become disintegrated on being subjected to the forces of agitation in the tank. After thus discharging the cake suction is again applied and the operation of filtration resumed; filtration continued until the surfaces of the medium are again sufficiently coated when the cake of solids may be discharged into the tank. This operation may be repeated until it becomes desirable to remove

preferably added to the sewage as it enters the treatment tank.

Numerous tests of the effluent obtained by this process from sewage rich in organic matter and harmful bacteria have shown the effluent in every case to be entirely free from organic matter and harmful germs.

Another unique method of operating the process, which it is sometimes found advantageous to employ, is to have a separate loading tank into which a "basket" of the filtering medium is first immersed for the purpose of forming a tum or cake of the precipitant thereon, by applying suction; when this cake has been formed on the surface of the filtering medium, the latter is then transferred and immersed in the treatment tank and the operation continued as previously described. This method is extremely effective in cases where wool scourers, tanneries, etc., add their wastes to the sewage.

Numerous demonstrations have proven that as soon as a

slight film of precipitant is formed on the surface of the filtering medium, a complete precipitation and separation of all the organic and foreign matter originally present in the sewage takes place and a clear, odorless and harmless effluent is obtained.

In operating the filters, the cake should be discharged in any of the various operating steps mentioned as soon as the vacuum gauge indicated a vacuum of 15 in., beyond which the rate of filtration rapidly diminishes.

The relative amount of moisture usually present in the discharged cake runs approximately 40 per cent, depending on the length of time the cake has been subjected to the drying action of the suction, while suspended in the air.

The chemical reagents used vary in accordance with the composition of the sewage undergoing treatment. In practice, sewage purification can be accomplished by the use of lime, copers, alum and caustic lime mud, the latter a calcium waste product in the alkali and paper trade.

In the construction of a plant wooden tanks have been found to be suitable, thereby doing away with the expensive iron or cement tanks at present used by disposal plants.

In comparison to the ground area required for installations of the different systems in use for sewage disposal, the great advantages of this process is clearly shown by the following figures:

Sand Filtration.—This system requires an area of one acre for about 30,000 gallons per 24 hours, operating under favorable conditions.

Continuous filters, the sewage having been previously treated either by chemical precipitation or by subsidence in settling tanks or in a septic tank, are assumed to be able to treat about 500,000 to 2,000,000 gallons per 24 hours.

The Chemproco (Chemical Process Company) system requires 230 square feet of surface area per 1,000,000 gallons per 24 hours. Besides this advantage, it is the only process delivering an effluent free from suspended matter, odorless and harmless.

The Chemproco system also possesses the following advantages over all others. It can be operated within the city limits without proving a public nuisance, and if desired it can be installed at the exits of the different sewers in cities where land values and local conditions render all other sewage disposal methods impracticable.

The process is operated by means of ordinary centrifugal pumps, driven by any desired motive power. The filtering medium with ordinary care will last from one to three years before requiring replacement.

No skilled labor is required: one man per shift can handle from one to thirty million gallons of sewage per day.

Preference is given to the recovery of the chemical reagents used in the Chemproco system from the discharged sludge. Experience has demonstrated that the regenerated reagents are not only more energetic in their precipitating qualities than the original chemical reagents, but that the rate of filtration is greatly accelerated.

The method of regeneration consists in calcining the sludge in a rotary kiln.

The operating cost of the Chemproco system ranges from \$5.50 to \$7.50 per million gallons of sewage.

Formastat is the trade name of specular hematite ore Fe_2O_3 , which after having been purified is sold as an imperishable paint pigment. It is particularly adapted for a paint for preservation of iron, steel, metals, woodwork, or any artificial surface exposed to the elements and the influence of destructive gases. The simplest formula for using it in making up 1 gal. of paint is 8 lb. formastat, 5 lb. pure boiled linseed oil, and $\frac{1}{4}$ lb. japan dryer.

Other formulas, as well as notes on application to aluminum, gold, and copper powders, together with general rules on the use of formastat, may be found in a pamphlet just issued by the manufacturer, the Formastat Mining Company, Twenty-first and Locust Streets, St. Louis, Mo.

Method of Producing Sound Ingots

Further Details of the New Process of Sir Robert Hadfield and Results Obtained with It in France.

In our November issue, 1912 (Vol. X, p. 738), we gave an account of a paper by Sir Robert Hadfield before the (British) Iron and Steel Institute on his new method for producing sound ingots.

We are obliged to Sir Robert Hadfield for the following information concerning the application of his method on a large scale.

By one plan the ingots are cast in molds placed upon bogies, movable trucks, or platforms, in the position A shown in Fig. 1. After casting the ingots vertically on bogies, the number on each bogie being as may be found most convenient, say four or more ingots on each bogie, advantage is taken of the time which elapses during transit of the ingots from the casting pit to the stripper to maintain the upper surface of the steel in a molten condition. This is effected by a series of air pipes, for example, three in number, with jets or holes on the under surface of such pipes, placed preferably horizontally arranged in such a manner as to cause jets of air to impinge at a suitable distance from the upper surface of the ingots. These holes or jets are made throughout the entire length of the overhead pipes, the length of such pipes being governed by the distance traversed under them by the bogies. In the figure shown the pipes are of sufficient length to extend over the tops of three rows of six bogies, each bogie containing four ingots.

One method of working is as follows:

As soon as possible after the ingots are cast, a quantity of charcoal sufficient for the purpose is placed on the top of each ingot, also a layer of insulating slag as described in the article referred to above. Although charcoal by means of the combustion effected by the heat of the molten steel delays to a certain extent the freezing of the molten steel, a blast of air applied to the charcoal generates a considerable amount of extra heat, this being of great advantage, as it helps to delay the freezing of the molten steel to such an extent that the good results before stated are effected in a manner which is impossible where such air blast is not used. The layer of slag, which may be termed an insulator, also prevents loss of heat and the charcoal is also prevented, or to a large extent so, from mixing with the steel, at any rate until too late to cause any interference with the quality of the product below the head portion.

If a series of bogies extending the length of the overhead pipes is used, the air blast may be working during the whole length of the piping, and if it should happen that only one or two bogies are in transit under the pipes it is not necessary for the air to be escaping throughout the entire length of the piping, but the air may be shut off in sections, and only allowed to escape in the section in which the bogies or ingots happen to be at the time being. Means may be provided for controlling the issue of air from each pipe to the ingots. Thus, each pipe may be formed at its lower side with a long slot or with a number of slots or apertures, and be provided with means, such as sleeves, which may be adjustable in a longitudinal or rotary manner, or in both a longitudinal and rotary manner, and by means of which the points of issue of the air to the ingot can be adjusted to suit requirements. Thus the air may issue between the adjacent ends of plain sleeves, or the sleeves may be furnished with suitably spaced nozzles, through which air can be caused to issue as required. As, however, it would be found that with normal working a continuous line of bogies would be passing underneath the air pipes—that is to say, there would be no break between the continuity of the bogies—the combustion, which is intensified and effected by the air jets on to the charcoal, would be effectively performed and carried out whether the ingots on the bogies were moving or at rest, owing to the continuity of the air holes or jets in the pipes which exert the pressure necessary for proper combustion of the charcoal being at what-

ever position the bogies and the molds may happen to be, provided they are within the range of the overhead air pipes.

It will thus be seen that if the passage of the bogies from the casting pit until they arrive at the stripper is relatively slow, the overhead air pipes need not be so long as in the case where the passage of the bogies from the casting pit to the stripper is at a more rapid rate, for it will be evident that in the latter case the overhead pipes would have to be of greater length than if the bogies were traveling under them at a slower rate.

Approximately the time that is necessary for the blast to operate on the upper surface of the molds, that is to say, from the time they are cast until the steel is sufficiently set to avoid any danger of piping, would be in the case of rail ingots from

casting for each individual ingot or for a group combined on one bogie or other suitable movable or stationary casting arrangement. The blast is continued as long as required; then the car or bogie is returned for further ingots to be cast.

It might be desired also to have a combination of bogies both worked electrically and by overhead pipes.

Fig. 1 shows the method of arrangement, which can be suitably varied to suit the local conditions. Although the sectional ingot shown is with the small end down, it can, of course, if preferred be cast with the small end up.

In Fig. 1 *A* is the plan of the casting department; *B* are drying stoves for heads, and *C* is a general plan of air pipes or blast arrangements, which are also shown in elevation by *D*.

Another method would be to make the casting plant circular

FIG. 1.—PLANS OF HADFIELD METHOD OF PRODUCING SOUND INGOTS

about fifteen to fifty minutes, according to the size of the ingot, though this time is only stated approximately. Also when the rate of progress is known at which the ingots move from the casting pit to the stripper—that is, the time from which the ingots are cast until they can be safely removed from their molds—the length of the overhead pipes can be easily calculated.

Three air pipes may also be used, these pipes being arranged at such a distance from each other as will enable the three rows of jets to play upon the molten steel which forms the heads of the ingots.

The height from the track to the upper side of the runner box should be approximately the same in every case, so that the air jets have the same heating effect on every ingot.

When the bogies arrive at the stripper the ingot molds are lifted and the ingots removed from the molds in the usual manner preferably retaining the ingots in a vertical position during the process of stripping. Considerable modification of this arrangement can be made as may be desired.

Ingots may be cast in this way with either their large or small end at the bottom, or with their large or small end at the top, whichever may be preferred, or practically parallel ingots may be produced of any size, section or shape which may be desired.

This method may be also applied to the production of castings of various types.

Another modification to effect the same object is by casting the ingot in molds upon bogies to which are attached electrically worked fans or blowers, the required electrical energy being taken from suitable overhead or underground cables. A blower of suitable type is mounted under the car at the side, or in such a convenient manner as may best suit the required purpose (see *F* Fig 2). As soon as the ingots are cast, the blower is put into operation, either while the car is standing still or as it moves along from the casting house. In this method a suitable supply of blast is obtained immediately after

—that is, the rails would be in a circular form outside the casting plant, and the bogies on which the ingots were cast could go around this if it were preferred to have the plant in this form.

In Fig. 2 *E* is a section of an ingot mold standing upon the bogie top, with air pipes in position at *X*; *F* the bogie arranged with the blower attached underneath as described.

The foregoing in a general way represents the methods of obtaining the desired advantages of preferably first obtaining sound steel which would pipe, then properly feeding the steel in such a manner as to give perfectly sound ingots with very little segregation portions, so that the double advantages are obtained of sound steel combined with much less waste than ordinarily experienced. Sound rails, bars or other forms are the result, with consequent advantage and increased safety to the user.

To obtain a sound and safe rail, the steel must itself be sound and free from blowholes. This requires the use of steel which will pipe or settle. As rail steel is now made, the maker has no proper means of adequately dealing with this property of fluid steel, namely, the "piping," often very deep, produced by "piping or settling steel." He therefore tries to avoid such steel, specially as it is dangerous unless the pipe is properly dealt with and fed, for the reason that in the methods hitherto generally adopted the pipe often runs down the center of the ingot for nearly one-half or even two-thirds of its length. By the Hadfield system piping itself is avoided, proper feeding being effected. Thus ingots are obtained in which soundness is ensured, that is to say, for example, in 10,000 ingots every one can be made sound and free from piping, blowholes and segregation.

It is suggested that this system should be thoroughly tested by the railroad companies in the following manner: Hadfield should supply a specified number of tons of ingots, say from 10 to 100 tons, as may be desired, made under this system; these should be rolled for the railroad, making the test by the

rail mill supplying the ordinary rails. Specimen rails selected from the batch would be tested by drop test or other mechanical means, in the manner carried out for the acceptance of rails under the present specifications.

Under the Hadfield system, too, the advantage is obtained of the investigator's long experience in alloy or special steels.

It is possible to produce, quite cheaply, special steel rails showing most excellent shock-resisting qualities, high dura-

size, weighing about 25 tons. Figs. 3, 4, and 5 show the results obtained.

M. Charpy stated that the Hadfield method of feeding the upper portion of the ingot in his special manner, namely sand head, air blast, charcoal, and insulating layer of slag, at-

FIG. 2.—MODIFIED PLAN OF HADFIELD METHOD FOR PRODUCING SOUND INGOTS

bility and other advantages, and this at little extra cost, that is, it is unnecessary to use expensive and costly steels such as high nickel, manganese or other similar types.

It is estimated that by the Hadfield method the cost per ton of sound steel fusible ingots is even less than that of fusible ingots made by the ordinary method, because the extra cost of the Hadfield treatment is more than counterbalanced by the fact that the discard with the Hadfield method is only 8 per

FIG. 3.—SECTION OF UPPER PORTION OF 25-TON INGOT

cent against 15 to 25 per cent with the ordinary method.

* * *

Quite unknown to Sir Robert Hadfield, the well-known French metallurgist, Monsieur G. Charpy, of the Cie des Forges et Acieries de Chatillon-Commentry et Neuves-Maisons, Montluçon (Allier), after reading the Iron and Steel Institute papers on this subject, decided to test the methods for himself, and proceeded to make an ingot of comparatively large

FIG. 4.—ANALYSIS OF INGOT AT DIFFERENT POINTS

peared to him to constitute a particularly simple and practical solution of the problem met with in steel manufacture, and to overcome the difficulties met with as regards piping, also reduce segregation and avoid the large percentage of waste material.

Fig. 3 represents a photograph taken by M. Charpy of the upper part of an ingot weighing 25 tons. This ingot had been treated by the Hadfield method, its composition being 0.40 per cent C, 0.02 S, 0.04 P, 0.45 Mn. The material also contained a small percentage of nickel.

Fig. 3 shows the satisfactory nature of the method. The portion of the ingot shown in the photograph represents about one-fourth of its total length. M. Charpy found that in order to eliminate all faults and sponginess in the ingot in question it was only necessary to cut off about 12 in. to 12½ in. from the upper part, in other words, about one-twentieth of the ingot, as against one-third which is the proportion of discard ordinarily required.

Moreover, the analyses taken of the material at different parts of the ingot showed this is free from segregation. Fig. 4 shows the parts from which the analyses given in table "A" were taken. Drillings were taken on the center line at the

FIG. 5.—DIMENSIONS OF 25-TON INGOT

different parts shown, commencing at the top, marked "A," also at the other parts as lettered.

Fig. 5 shows the dimensions of the 25-ton ingot referred to. The waste and segregated material in this ingot only amounts to about 5 per cent of the total weight.

The original (British) Iron and Steel Institute paper of Sir Robert Hadfield on his process was published in our November issue, 1912, p. 738.

Some Notes on the Manufacture and Properties of Carbon Bricks.*

The resistivity of amorphous carbon against high temperatures, abrupt changes of temperatures, and not the least against chemical corrosion by ashes and slags make it especially valuable for manufacturing refractory material for smelting furnaces.

For this purpose carbon is used in form of coke which should be as much free from ashes as possible. The raw material, prior to molding, is made up in different ways. According to an older method, which is scarcely in use any more, the crushed coke is mixed with a small proportion of clay, this being in suspension in water. In the new method, now universally applied, the dried coke is crushed to grains of 1 mm. size, sieved and thoroughly mixed in the pug-mill with about 20 per cent in weight of heated tar.

The plastic mass thus prepared is filled, in successive layers, into wooden or iron molds, by taking care to create the upper surface of the last applied layer in order to secure a perfect bond between the different layers. In this operation care should be taken to fill the molds up completely, and to drive the mass into all the corners so as to obtain a brick with plain and even surfaces and sharp corners.

By following this precaution only a narrow joint will be left between adjacent surfaces of the bricks when laid aside in a wall. The drying of the wet bricks requires about two weeks, which is effected in the open air, after which they are ready to be burnt.

The bricks are then set in a producer-gas fired chamber-kiln and are enclosed in fireclay saggars. The spaces left in these saggars are then completely filled up with pulverized coke. The use of this filling is to protect the carbon of the bricks from any contact with air and combustion gases of the kiln, and to prevent combustion of the carbon.

In the average a burning temperature corresponding to Seger cone 12 is required. The tar content of the brick carbonizes during the burning and the additional carbon thus formed unites with the coke to form a strong and homogeneous mass. The specific gravity of carbon bricks varies from 1.5 to 1.9; the ash contents, in average, amounts to 12 per cent.

As stated above, these carbon bricks are exclusively used in metallurgical plants. They render excellent services for lining lead melting furnaces and other metallurgical furnaces where oxidation of the molten metal is to be prevented. Special attention has been given to carbon bricks in the construction of some parts of blast furnaces, where they are used for lining both walls and bottom. According to numerous reports carbon bricks showed in this instance a most satisfactory behavior, which, as in many other instances, depends mainly upon careful manipulation and treatment.

As few and as narrow joints as possible should be made in laying carbon bricks, otherwise the molten metal would enter the joints and cause loosening of the lining.

A mortar made up of pulverized coke with 20 per cent of good fireclay has been successfully used. This mixture, after being ground to a minute powder, is stirred up with pure water, i. e., which should be free of any soluble salts, to the consistency of a slip and this just before being used as mortar. It is essential for guaranteeing durability of the masonry to allow the same to dry slowly and thoroughly.

After all the water contained both in mortar and bricks is expelled, the furnace then may be put in service, otherwise mortar as well as bricks will be dislocated by a too sudden evaporation of the water. The solidity of the carbon brick masonry requires the application of a special and proper outside shell extending over the bosh and the hearth portions of the furnace.

The opinions about unlimited solidity of carbon bricks in metallurgical furnace practice differ, according to observers and circumstances. As to Dr. Ing. C. Geiger, in No. 41 of

Stahl und Eisen, 1912, carbon bricks showed especially good results in the production of high-carbon gray iron. Again, the fitness of this kind of bricks for foundry iron has repeatedly been confirmed; also successful results have been obtained with them in connection with Thomas iron.

These favorable reports have, however, been opposed by the testimony of other metallurgists who observed evident failures in several instances, so that the carbon bricks soon disappeared when in contact with so-called white pig iron and Thomas iron. A complete explanation of these failures has not yet been given, so far as the actual observations go. According to Mr. v. Schlippenbach this is probably due to the greater indirect reduction of the iron oxides by the carbon or that the iron with normally low carbon percentage readily combines with that of the carbon lining.

In order to elucidate this question further it would be a valuable undertaking for manufacturers of refractories as well as for metallurgists if accurate observations and systematic tests would be made and published.

Notes

The order in which the stamps drop in the Homestake mills is 1-3-5-2-4, or what is the same thing, 1-4-2-5-3. This order has been tested with other variations, such as 1-5-3-2-4 = 1-3-4-2-5, and has been found to give a slightly greater daily tonnage.

The extent to which gold penetrates copper plates in amalgamation has been investigated by Clark and Sharwood (Bulletin 98, Inst. Min. & Met.), who found that beyond a depth of 0.005 in. from the face of the plate nearly all the value lay in dents and pinholes. The percentage of gold found in layers next the surface, totalling about 1/64 inch, was 98 per cent. The value of gold contained in a square foot of outside plate was \$0.31; of a chuck-block plate, \$1.11.

Potash explorations in Nevada and Nebraska have disclosed deposits of potential value in both states. In Nevada the Silver Peak marsh was drilled and found to yield salts containing as much as 3.5 per cent K_2O . Certain shallow lakes in the sand hills of western Nebraska also contain potash in solution as well as in the surface of the lake beds.

Developed ore in the mines of the main reef series of the Witwatersrand is estimated at from 100,000,000 to 110,000,000 tons. At the present crushing capacity of Rand mills this ore constitutes a reserve sufficient to last for three years.

Protecting Exposed Metal Work in Battery Rooms.—No metal work in a battery room, especially over the cells, should be exposed to the action of the acid fumes and gases. The structural iron work of the building can be very well protected by encasing it with expanded metal work upon which a coating of cement plaster is placed. This if kept well painted with a good lead paint will prove a very satisfactory way of protecting all structural metal work. Pipes and small portions of metal work can be protected by sheet lead, or if they are not in too close proximity to the cells can be protected sufficiently by frequently cleaning and painting with an acid resisting paint such as Hydrex preservative paint. This paint is very thick and heavy, and forms a strong, heavy protective coating, and does not contain any coal tar to corrode the metal. It is claimed to be acid, gas, and sulphur fume-proof. The battery rooms in all new electric sub-stations of the New York Central Railroad are painted with this preservative paint. One great danger of exposed iron work in a battery room if it extends over the battery, is that the sulphate of iron formed by the action of the fumes may fall into the cells and impair the purity of the electrolyte, thereby seriously damaging the plates.

The *Biddle Bulletin* is the title of a new trade publication issued by the Biddle Hardware Company, of Philadelphia, Pa., to give information on new developments in the Monel metal market.

* Translated from the *Thomson Zeit.*, by Leon V. Schleich.

Ore Sampling Without Machinery

A Series of Instructive Illustrations
Explaining the Essential Feature
of Ore Sampling. By Jesse Scobey

CORRECT sampling is the basis of ore valuation; an assay can represent only the proportionate value of the sample tested. These two propositions are recognized as fundamental by competent technical men, and yet occasional evidence is found which indicates that these principles are violated even by those who should know better, not to mention those whose lack of training and experience lead them into costly errors. Perhaps the self-evident nature of the requirements of correct sampling is one reason why comparatively little attention has been paid to the subject in technical literature. Hence no apology is required for reiterating some facts which cannot be too strongly

mixed with the proper amount of suitable fluxes, and smelted in a sufficiently large furnace, it would yield exactly 10 oz. of silver, about the size of six silver dollars. This would be a perfect assay; but manifestly it is impossible to work on so large a scale, and the practice of assaying limits the amount of ore used to an assay-ton, which is a quantity slightly more than 1 oz. It is, then, essential that this small amount of ore should be exactly representative of the ton. By delicate balances the actual amount of silver smelted from the amount of ore used is weighed, and by proportion the amount per ton is calculated. The whole secret in the proper valuation of a ton

FIG. 1.—A PILE OF 400 LB. OF ORE

FIG. 2.—HAMMER CRUSHING

borne in mind. An assay is worthless unless the sample is representative, as many a man has learned with regret.

It frequently happens that laymen who are interested in mines, or who desire to investigate mining propositions in a tentative way, resort to the practice of taking their own samples for assay. The results may be disappointing or highly encouraging, but are worthless unless the sampling has been performed properly. If the ultimate result is unsatisfactory, it is customary to claim a discrepancy in the assay without realizing that the error possibly lies in the sampling. This is an old subject, well understood by some, but may be repeated for the benefit of those not familiar with the technique of mining.

In order to appreciate the relation of assaying to correct sampling, let us consider briefly the conditions surrounding the former operation. In assaying, the results are reported in ounces of gold or silver per ton of ore; that is, a ton of the ore in question would contain one or several ounces of gold or silver. With silver worth 64 cents per ounce, an assay of 10 oz. silver per ton means that a ton of such ore would contain silver to the value of \$6.40. If a ton of this ore should be

of ore is, then, simply to get a correct sample of it, weighing not more than a few ounces.

Sampling without machinery¹ requires not only manual labor, but the exercise of care in order to approximate the accurate results which can be obtained with mechanical appliances. If a ton of ore can be sent to a testing or sampling works equipped with crushers and samplers, the work is simple indeed. Many mine operators, engineers and others engaged in mining have not these facilities, and do not care to incur the expense of sending ore to the testing works. In order to accomplish the same result by hand-sampling there need be only a full realization of the fact that the ore must be broken finer and finer at each successive stage of the process, as the remaining sample becomes smaller.

The illustrations herewith will convey the idea better than a lengthy description. The pictures show the successive steps in sampling a lot of crude ore.

Fig. 1 shows a pile of 400 lb. of ore. It was broken from a

¹Brunton has described and illustrated the possible errors in coning and quartering. *Transactions A. I. M. E.*, Vol. XL, p. 567.

vein, the value of which is to be determined by assay. When a representative sample is desired, it is inadvisable to start with less than 400 lb. of ore.

Fig. 2. Using a sheet canvas, an anvil or heavy piece of iron and a heavy hammer, break each piece of ore to less than

pile or bed several inches thick. Then throw one shovelful to the "sample" pile and three shovelfuls to the "reject" pile, making a sample which shall be one-fourth the size of the original pile. Each piece of ore in the "sample" should be one-fourth or less of its original size.

FIG. 3.—SHOVELING INTO A CONE

FIG. 5.—CRUSHING SAMPLE WITH HAMMER TO NUT SIZE

fist-size. Scatter the pieces well over the canvas to be sure that all are broken.

Fig. 3. With a square-pointed shovel throw all the ore into a central pile or cone, dropping each shovelful precisely in the

Fig. 5. We now have about 100 lb. in the sample. Take a hammer and again break each piece of rock to less than nut-size. Thoroughly spread and mix this portion as before.

Fig. 6. The sample is again carefully coned, and flattened by

FIG. 4.—SAMPLE PILE OF 100 LB. AND REJECT PILE

FIG. 6.—FLAT CAKE

center. This is a precaution that must be observed in order to distribute the coarse and fine ore uniformly on the pile.

Fig. 4. By working around the pile with the shovel, draw the center to the sides in order to mix evenly the fine and coarse particles. The cone is thus transformed into a flat

tamping down the top. This gives a flat cake which can be marked into quarters by means of a board and shovel.

Fig. 7. By shovelling away opposite quarters we leave a sample weighing about 50 lb., while the 50 lb. of "reject" can be discarded.

Fig. 8. The same operation described under Fig. 5 must now be repeated, breaking each piece to pea-size or smaller, spreading the ore over the canvas to be sure that all pieces are broken.

Fig. 9. Shovel the sample into a cone again, carefully clean-

at the left on the table; reject one portion and again divide the other. One portion of this last division will weigh about 2 or 3 lb.

Fig. 12. Repeat the grinding operation shown in Fig. 11 until the sample will pass an 80-mesh screen. Divide the sample

FIG. 7.—REDUCING SAMPLE TO 50 LB

FIG. 9.—CONING AGAIN

ing the canvas with a broom so as to be sure that no fine ore is lost.

Fig. 10. Flatten the cone, mark into quarters, and with a small fire-shovel remove opposite quarters. Remix the remain-

twice as before, when the final portion will weigh about 8 oz and will fairly represent the original 400 lb. This is a safe and sane sample for the assayer.

FIG. 8.—BREAKING TO PEA SIZE

FIG. 10.—REDUCING SAMPLE TO 10 OR 12 1/2 LB

ing ore; cone and quarter again. The sample will now weigh about 10 or 12 1/2 lb.

Fig. 11. This sample must now be ground on a bucking-board until fine enough to pass a 10-mesh screen (openings about 1/20 in.). Pour this fine ore through a divider, shown

The procedure just described may be subject to modification for different grades of ore, richer ores requiring finer subdivision in the successive steps so that the whole mass may be more intimately mixed. The following table shows the maximum size of particle that should exist in the different portions

as the quantity retained for the sample decreases. Column A refers to a medium-grade ore; column B to a high-grade ore, and column C to a very rich ore.

FIG. 11.—REDUCING SAMPLE TO 2 OR 3 LBS.

Quantity of ore to be sampled.	A Size.	B Size.	C Size.
100 tons to 10 tons.....	3 1/4 in.	3 in.	2 1/2 in.
10 tons to 1 ton.....	2 1/2 in.	1 1/2 in.	1 1/4 in.
2000 lb. to 200 lb.....	1 in.	3/4 in.	3/2 in.
200 lb. to 5 lb.....	5/16 in.	3/16 in.	5/32 in.
5 lb. to 8 oz.....	1/32 in. or 16-mesh screen	1/64 in. or 30-mesh screen	1/164 in. or 80-mesh screen

FIG. 12.—REDUCING SAMPLE TO 8 OUNCES

Consideration of the foregoing will show that the cost of concentrations and accurate sampling is greater than is sometimes conceded to be a reasonable charge. Engineers and laymen should recognize the importance of a properly taken sample and should insist upon it; otherwise there will be a mis-

conception of the value of the ore, and dissatisfaction when it is shipped to the testing works, mill or smelter.

A "mill test," so-called by the old-time prospector or miner, is nothing more than the shipment of about 400 lb. of ore to an assayer who, with proper facilities, crushes and samples the lot to obtain a representative portion for assay. A common charge for this work is from \$1 to \$5. Anyone can do it in the field by following the above procedure, realizing that time, labor, and care are essential.

The Henry E. Wood Ore Testing Company, Denver, Col.

An Application of the Electric Resistance Furnace to the Determination of Oxygen in Iron and Steel

By R. H. McMillen

The fact that iron and steel always contains more or less oxygen has long been known, and about thirty years ago Ledebur¹ called attention to it and gave a method for its determination. It is only recently, however, that the requirements in the manufacture of high-grade steels have become so exacting that the determination of oxygen in steel and other materials has come to be one of the routine determinations required of a steel laboratory.

The Ledebur method, which is well known, consists in heating the sample of iron or steel in nitrogen to remove all moisture without oxidizing it, then reducing the oxides at a red heat by hydrogen and absorbing and weighing the resultant water. Cushman² has shown that the drying of the sample in nitrogen is unnecessary, his results being but slightly higher than those by the original method. When used with electric resistance furnaces, this method is very satisfactory for the determination of oxygen in iron and steel, tungsten³, and other non-volatile metals. Even this method, however, will fail to show all the oxygen in metals containing oxides of silicon, vanadium, titanium, and other elements whose oxides are not reduced below 950 deg. C.⁴

The following modification of the Ledebur method has been found to give most satisfactory results:

Apparatus.

The apparatus consists of two electric resistance furnaces, such as are employed in many steel laboratories for combustion carbon determinations and capable of maintaining a temperature of 950 deg. C.

They are designated as No. 1 and No. 2 in Fig. 1. Both furnaces are equipped with heavy walled, fused quartz tubes 7/8 in. inside diameter by 24 in. long. The function of furnace No. 1 is to heat the sample under investigation, while that of No. 2 is to heat the hydrogen so that it may combine with any oxygen that may be carried over from the hydrogen generator. Several spirals of platinum gauze are placed in the quartz tube of this furnace.

The quartz tubes of these furnaces are connected in the rear by a U tube (not shown in the illustration) having close fitting glass stop-cocks. This U tube is filled with phosphorus pentoxide opened by small glass beads. The phosphorus pentoxide absorbs any water which may be formed in tube of furnace No. 2, and insures absolutely dry hydrogen to pass over the sample in furnace No. 1. The front end of the quartz tube in No. 2 furnace is connected to the drying and purifying train leading from a hydrogen generator.

No. 3 contains small pieces of pumice stone saturated with concentrated sulphuric acid, No. 4 soda lime, No. 5 stick potassium hydrate, No. 6 50 per cent solution potassium hydrate, No.

¹Sauerstoffbestimmung im schmelzbaren Eisen. Stahl und Eisen, Vol. 2, page 193.

²The Determination of Oxygen in Iron and Steel. Journal Ind. and Eng. Chem., Vol. 3, page 372.

³Tungsten powder often contains a rather large percentage of oxides. Some commercial samples investigated by the writer recently have shown an oxygen content corresponding to 12% WOs. It is probable, however, that the whole of the oxygen is not combined with the tungsten.

⁴See The Determination of Oxygen in Iron and Steel by Reduction in an Electric Vacuum Furnace by W. H. Walker and W. A. Patrick. Met. and Chem. Eng'g, Vol. 10, p. 629. Original Communications of Eighth Internat. Congress of Applied Chemistry, Vol. 21, p. 139.

7 25 per cent solution of pyrogallol made alkaline with potassium hydrate.

Hydrogen is generated in a sixty-four ounce Kipp apparatus by the action of chemically pure hydrochloric acid on pure mossy zinc.

The water formed by reduction of oxides in the sample is absorbed in U tube No. 9 of same construction as No. 8, and also filled with phosphorus pentoxide opened with small glass beads. A guard tube, No. 10, is attached to No. 9 and contains concentrated sulphuric acid. A small wash bottle of Drexel form is used for this purpose. Porcelain boats of sufficient size to hold at least twenty-five grams of the sample are employed.

Preparation of Sample

Great care must be taken in preparing the samples so that they be free from rust or foreign oxides. In the case of iron or steel samples both the fine and coarse drillings are rejected, only those between twenty and thirty mesh being used. These

FIG. 1.—APPARATUS FOR DETERMINATION OF OXYGEN IN IRON AND STEEL BY A MODIFIED LEDEBUR METHOD

are dried for at least one hour over concentrated sulphuric acid before using. Samples of tungsten powders are dried to a constant weight in the drying oven at a temperature of 105 deg. C.

Procedure

Twenty-five grams of the prepared drillings are weighed into the dried porcelain boat and placed in tube of furnace No. 1. Connection is made to weighed U tube, No. 9, through which, just previous to drying for fifteen minutes and to weighing, hydrogen has been passed for ten minutes. Guard tube No. 10 is connected. Hydrogen is allowed to pass through the whole apparatus at a rapid rate for fifteen minutes. For the first run it is advisable to allow the hydrogen to sweep through the whole apparatus for thirty minutes to insure complete expulsion of oxygen from the train and tubes. The train and quartz tube of furnace No. 2 can be kept constantly filled with hydrogen by closing cocks of U tubes No. 8 whenever the flow of hydrogen is interrupted.

The electric current is turned on and continued for one hour after the maximum temperature has been reached. During this time the flow of hydrogen is cut down to about seventy bubbles per minute, this rate being maintained until U tube No. 9 is removed. At the end of the hour the current is turned off and furnaces allowed to cool, accelerating the cooling with a blast of compressed air. When the quartz tubes in the furnaces show no visible redness, cocks of U tube No. 9 are closed and a pinch cock is inserted over the rubber tube connecting U tube No. 9 to the quartz tube of furnace. In this manner oxygen is kept from the heated tube thereby avoiding danger of explosion. U tube No. 9 is disconnected and carefully wiped with soft dry cloth then desiccated over concentrated sulphuric acid for fifteen minutes and finally quickly weighed. Weight of water, after deducting blank, multiplied by 0.8888 divided by 25 equals oxygen.

A blank should be run frequently, adhering to all details as to time of heating furnaces, desiccating U tube, etc. Usually the blank found varies between 0.0015 and 0.0025 gram.

For samples of tungsten powder the same procedure is carried out except that a smaller sample is taken varying from one to ten grams according to amount of oxygen present.

The following table gives results on several samples in duplicate by the above described procedure

No.	C	Fe	Mn.	Sul.	Phos.	Si.	O.	Dug. i. cate.
1	Crucible steel	1.15	.31	.018	.011	.21	.03	.037
2	Crucible steel	1.17	.31	.015	.010	.22	.03	.035
3	Crucible steel	1.14	.33	.016	.009	.2	.044	.045
4	*Basic open-hearth steel	.07	.06	.019	.008	.18	.113	.115
5	Basic open-hearth steel	.08	.22	.016	.008	.21	.172	.17
6	Swedish wrought iron	.06	.17	.019	.012	.1	.345	.353
7	Domestic wrought iron	.69	trace	.009	.007	.06	.069	.76
8	Domestic wrought iron	.73	trace	.009	.007	.06	.090	.89
9	Acid open-hearth steel	.36	.66	.040	.046	.03	.641	.042
10	Bessemer steel	.46	.72	.041	.095	.09	.658	.060
11	Tungsten powder	..	..	..	..	..	2.27	.57
12	Tungsten powder	..	..	..	..	..	1.37	1.34
13	Tungsten powder	..	..	..	..	..	.55	.56
15	Tungsten powder	..	..	..	..	..	..	1.45

Numbers 1, 2 and 3 were three ingots made under as nearly the same conditions as possible. It is not intended that the above table should be typical as to the oxygen content that exists in the different classes of steel. In many samples of crucible steel it is much lower than those cited.

*This sample fractured badly in rolling.

Crescent Laboratory,

Crucible Steel Company of America.

Swedish Methods of Packing Ferrosilicon

Two Swedish manufacturers of ferrosilicon export their product to the United States. Their methods of packing the product have been secured by Consul Stuart J. Fuller, Gottenborg, and transmitted to the United States Bureau of Commerce and Labor. The method of the Gullspanns Elektrokemiska Aktiebolag are as follows:

"For packing we principally use iron-bound wooden cases in two sizes, one (for 50 per cent ferrosilicon) containing about 130 kilos (287 lb.) and one (for 75 per cent) holding about 110 kilos (353 lb.). The boxes have always been unlined and were made in the beginning of un rabbeted $\frac{5}{8}$ -in. stock, but since last year we have employed rabbeted stock, as the loss of contents in transit was found to be too great with un rabbeted boards. Water-tight packing being required for Germany, we pack goods for that country in second-hand kerosene barrels; these are, of course, both water and gas tight, but no fault has been found with them. On all our very latest shipments we have, at the request of foreign sellers, begun to pack ferrosilicon in sheet-metal cylinders containing about 170 kilos (375 lb.), and have made four holes of 7 mm. (0.276 in.) diameter in the top to provide against excessive pressure in the cylinders.

"It will be seen from the foregoing that the regulations in force are different for different countries (e. g., for transport on some English railways each package must have three 1-in. holes to permit the escape of any gases that may form). In our opinion, the dangers connected with the transportation of ferrosilicon can never be entirely avoided until uniform international regulations are adopted. In this connection it should be noted that danger is present only when the material has a silicon content between 35 and 65 per cent; under and over these proportions ferrosilicon is much more stable. So far as we are informed, accidents have never happened except with ferrosilicon of about 50 per cent silicon content. If, as we hope, an international regulation regarding packing and transportation of high percentage ferrosilicon can be established, regard should be had for the last-mentioned fact, and different regulations adopted for 25 per cent, 50 per cent, and 70 per cent goods or those of higher percentages.

Four Styles of Package Used by Another Firm

"The Aktiebolaget Heroult's Elektriska Stål thus describes in detail its methods of packing ferrosilicon:

"Until recently we used wooden barrels as containers for ferrosilicon. These barrels consisted of:

"(a) Old oil barrels and tar barrels, etc., holding about 500 kilos (1100 lb.) of 50 per cent ferrosilicon. These barrels we would describe as tight with exception of the cover, which is made of rough boards laid edge to edge without rabbets and held together by two laths. Across the cover are then nailed

two pieces of hoop iron, the ends of which are turned down and nailed to the sides of the barrel.

"(b) Wooden barrels, which hold about 700 kilos (1543 lb.), shaped as cylinders and made of 1-in. rough and un rabbeted boards, which have the edges cut aslant so that they fit or overlap each other in the sides of the barrel. The bottom and the head are made as described under (a).

"(c) The last few months we have used barrels taking about 300 kilos (660 lb.) and made in the same way as those described under (b), but of $\frac{3}{4}$ -in. boards instead of 1-in.

"(d) Barrels holding about 300 kilos (660 lb.) and consisting of cylinders of 0.6-mm. (0.0236-in.) sheet iron. The rolled or folded seam is reinforced with rivets. The head and bottom are made of wood, as described under (b), but of rough boards, and are placed so far inside the cylinder that the rims of the same can be turned over the bottom and cover about $\frac{1}{4}$ in. Head and bottom are fastened by nails driven through the wall of the cylinder and into the wood.

"We use only barrels, which can be rolled and therefore are more convenient to handle when moved than would be the case with another form of package—boxes, for instance. Besides this, the round form is stronger with the same thickness of walls.

Advantages and Disadvantages.

"With reference to the packing according to (a) and (b), these packages proved too heavy to handle with ease, and therefore we changed to packing (c). As, however, the packing (c) costs more for a certain quantity of ferrosilicon than the packings (a) and (b) and also increases the weight of the tare and consequently the freight that has to be paid per ton of iron, we have during the last few weeks partly adopted the packing (d).

"The forms of packing (a), (b) and (c) have this disadvantage, that when the packages have been stored for some time the wood has dried and shrunk, causing cracks between the staves as well as between the staves and the head or bottom, and these cracks have been large enough to let some of the ferrosilicon powder fall out. Some ferrosilicon has always a tendency to fall apart into powder or dust, and such powder is also formed when the packages are handled. Therefore, when the barrels are rolled, chiefly in transit, some of the pulverized ferrosilicon can fall out through the cracks, causing disagreeable controversies between seller and purchaser concerning the net weight.

"We consider that this inconvenience is most easily avoided by using the packing (d), for in this the walls do not allow any powdered ferrosilicon to escape, and the rims of the cylinder, turned over the edges of head and bottom, also prevent loss of powder between the wood and the metal wall of the cylinder. According to our opinion, this advantage is obtained with packing (d) without preventing ample ventilation in the barrels. Should it, contrary to our supposition, be shown that this ventilation is insufficient, holes can easily be made in the center of head and bottom, and these holes can be covered with wire-cloth, perforated metal sheets, or strong bagging."

Tungsten-Molybdenum Thermocouple.—In Dr. E. F. Northrup's article in the January issue, page 45, the sentence beginning in the eighth line of the second column should read: "At 1000 deg. C. (instead of 100 deg. C.) the oxidation is negligible, etc."

Cement Floor.—"The best hardening preparation for a cement floor is composed of equal parts of care, cement, and water used when the floor is built," states Leonard C. Wason, president of the Aherthaw Construction Company, of Boston, in a recent paper. "Various advertised products have been tried out, and there is considerable divergence of opinion. Certainly none of them have had uniform success, as could hardly be expected, under varying degrees of intelligence in their handling. So far as our experience goes we do not know of anything better than a floor made with properly selected stone and cement, laid intelligently and properly protected."

Specifications for Open-Hearth Steel Blooms, Billets and Slabs for Forging Purposes.

The Association of American Steel Manufacturers has just issued a set of "Standard Specifications for Open-Hearth Steel Blooms, Billets, and Slabs for Forging Purposes."

The need for standard requirements governing the chemical and other properties for forging billets has been apparent for some time and the new specification may be expected to be used widely in this field. A feature that is distinctly new is the table of allowable variations on check analysis of carbon, manganese, and other elements. In giving this table out for general use the Association of American Steel Manufacturers is taking a bold step toward standardization. Mr. A. A. Stevenson is the president and Mr. Jesse J. Shuman, care of Jones & Laughlin Steel Company, Pittsburgh, Pa., is the secretary of the association.

The new specifications are as follows:

I. Manufacture.

1. *Process.*—The steel shall be made by the open-hearth process.

2. *Discard.*—A sufficient discard shall be made from the top of each ingot to secure freedom from injurious piping and undue segregation.

II. Chemical Properties and Tests.

3. *Chemical Composition.*—The steel shall conform to the following requirements as to chemical composition:

Element.	Class.	Least Range to Be Specified.	Allowable Variation on Check Analysis Outside of Range Specified.	
			Under.	Over.
Carbon	Up to .10, .11 or .12	...	...	.02
	.10 to .25	.05	.02	.05
	.26 to .60	.10	.02	.05
	.61 to .90	.15	.02	.08
Manganese	Up to .60	.20	.05	.05
	.61 and over	.30	.05	.05
		Least Maximum to Be Specified.		
Phosphorus		.040	...	.010
Sulphur		.045	...	.010

4. *Class.*—The class shall be determined by the upper limit specified for carbon and manganese.

5. *Ladle Analyses.*—To determine whether the material conforms to the requirements specified in section 3, an analysis shall be made by the manufacturer from a test ingot taken during the pouring of each melt. If requested, a copy of this analysis shall be given to the purchaser or his representative.

6. *Check Analyses.*—Check analyses may be made by the purchaser in accordance with the standard methods of sampling for check analysis adopted by the Association of American Steel Manufacturers, and these analyses shall conform to the requirements specified in section 3.

III. Workmanship and Finish.

7. *Chipping.*—Chipping shall be done in such a manner as not to cause any imperfections when the billets, blooms and slabs are properly forged.

8. *Finish.*—Billets, blooms and slabs shall be free from all injurious defects.

IV. Marking.

9. *Marking.*—The melt number shall be legibly stamped on each billet, bloom and slab.

V. Inspection and Rejection.

10. *Inspection.*—(a) The inspector, representing the purchaser, shall have free entry at all times while work on the contract of the purchaser is being performed, to all parts of the manufacturer's works which concern the manufacture of the material ordered. The manufacturer shall afford the inspector, free of cost, all reasonable facilities to satisfy him that the material is being furnished in accordance with these specifications.

(b) The purchaser may make the tests to govern the accept-

ance or rejection of material in his own laboratory or elsewhere. Such tests, however, shall be made at the expense of the purchaser.

(c) All tests and inspection shall be so conducted as not to interfere unnecessarily with the operation of the works.

11. *Rejection*.—Billets, blooms and slabs which show injurious defects while being finished by the purchaser may be rejected, and the manufacturer shall be notified.

12. *Rehearing*.—Samples tested in accordance with section 10 (b) which represent rejected material, shall be preserved for one month from the date of the test report. In case of dissatisfaction with the results of the tests, the manufacturer may make claim for a rehearing within that time.

Recent Advances in the Spray Process for the Production of Metallic Coatings

By M. U. Schoop

In spite of the extraordinary simplicity of the principle which underlies the spray process for the production of metallic coatings, which I described in an article in this journal in July, 1910 (vol. VIII, p. 404), careful experiments extending over several years were necessary to transform the original idea of the invention into a practically successful process.

In order to be practically successful, the apparatus must be capable of being started or stopped at any time within a few minutes and the necessary materials must be easily procurable anywhere. Further, the apparatus must be easily movable so that even objects of large dimensions, wherever they may be located, can receive a cheap and durable metallic coating.

This goal has now been reached. Coatings of all metals, of the easily fusible tin and lead, as well as of copper, iron, platinum, can be made with the spray process.

The first experiments were made with a Flobert rifle. Experiments with small cannons followed whereby powdered lead or tin was sprayed. In some of the experiments the charge of ground metal in the cannon was carefully heated and melted by means of an alcohol lamp. Though these experiments were rather primitive, they showed, nevertheless, that the problem could be solved in two ways. Either molten metal could be sprayed or metallic powder could be used if only the powdered metallic particles were given a large kinetic energy. For this reason the first patents alluded expressly to the use of either fluid metal or metallic powder (Swiss patent 49,278, of November 26, 1909).

Spraying Liquid Metal

It is evidently difficult to design an apparatus in which metal is molten and sprayed so that it can be easily and quickly put into operation. It is even more difficult to make it movable, while with a stationary apparatus the application of the process would be considerably limited.

It is not difficult to build apparatus of this kind on a small scale so that large molten baths are avoided. But such apparatus involve essential and inherent difficulties, of which one of the most troublesome is the tendency of the molten metal to alloy with the crucible and the spray nozzle. The formation of alloys seems to be aided considerably if the molten bath is under pressure and if high temperatures are used. With easily fusible metals, crucibles of soft steel can be used, while with aluminium, brass, and copper only graphite or carbon fulfills to some extent the requirements. The spray nozzle cannot be made of copper nor of metal.

We succeeded in overcoming these defects by employing as container for the molten metal a closed armored crucible, to the interior of which either a pressure or a vacuum may be applied at will by simply turning a handle. If the molten bath is put under pressure the molten metal is ejected in form of a capillary uniform filament, while when a partial vacuum is applied the ejection of metal stops. This pneumatic device has the advantages that the apparatus can be started or stopped at any time. My French patent 411,100 contains a diagram which illustrates the operation of this apparatus.

This apparatus was the final result of a large number of experiments and undoubtedly represented a considerable advance since it was now possible to spray and deposit metals at any melting point. These pneumatic melting crucibles, however, are not particularly easy to handle or to transport.

In this article it is not possible to describe in detail the experiments which have been made in my Zurich laboratory with this melting crucible. It may only be stated that the conditions of operation, especially the amount of pressure and vacuum in the crucible, the design of the spray nozzle, the pressure and the temperature of the metal to be sprayed, etc., must be different for different metals. For every metal the application of the process must be worked out separately.

A characteristic feature of the metallic coatings which are obtained by spraying liquid metal seems to be that the metal increases in hardness and loses in ductility, and according to our experiments it does not matter much whether compressed air or steam, or hydrogen, or nitrogen gas is used. It might have been thought that the phenomenon is due to oxidation, but the same results are obtained if non-oxidizing gases are employed so that any oxidation of the metal from the spray nozzle to the surface to be coated is avoided.

Spraying Metallic Powder.

In a series of further experiments metallic powder or metallic dust was sprayed with great force. In this case the process may be aided by heating the metallic powder or the gas or the surface to be coated. If, however, the kinetic energy of the metallic particles is large enough, no flame or other method of heating is required with certain metals. This surprising result is probably due to the fact that the metallic particles shot upon the surface with great speed (great pressure) get heated momentarily and are thereby welded together.

In the apparatus described in German patents 252,565 and 253,510 the metallic powder is blown in an adjustable quantity by means of compressed air to the spray nozzle and is then blown through a concentrically arranged blow lamp flame. With lead, tin, and zinc, compressed air and illuminating gas are used. With metals which are not so easily fusible oxygen must be employed.

In this process it is important to avoid overheating as this would cause evaporation of the metal. On the other hand, if the temperature is insufficient or not uniform the different particles do not weld together into a uniform and intimate coating.

Very promising results have been obtained so far, especially with tin and zinc coatings, as described in the *Chemiker Zeitung*, 1911, No. 155, p. 1434. It may be mentioned that the new zinc coating process has been introduced on a large scale in several factories in Belgium and France and also in the French Navy.

Coating with lead by this process is also successful if non-oxidized lead powder is used. This condition, however, is not easily fulfilled in practice since lead powder oxidizes when in contact with air.

The Latest Development of the Spray Process.

An observation which was made incidentally in the spring 1911, led finally to a new method which is different in principle from our former methods. The fundamental idea is to melt from a metallic strip or wire only such a small quantity of metal as is to be sprayed at any moment. Fig. 1 illustrates the principle; *c* is the surface to be coated; *a* is the metal from which the coating is to be made. It is placed within the guide cylinder *b* and is being pushed uniformly forward so that its lower end is molten off by means of the flame *e*.

The drops which form in rapid succession are finely subdivided by means of the "transportation wind" blown through the pipes *d* and are thereby shot upon the surface *c* where they weld together and form a beautiful metallic coating. The thickness of the coating is practically proportional to the time of the spray operation. The gas pipe for the flame and the pipe for the "transportation wind" may also be arranged concentrically, as shown in Fig. 2.

The pressure to be used and the chemical nature and temperature of the flame depend primarily upon the nature of the metal to be sprayed and the same is true for various other factors like the speed with which the metal to be sprayed is pushed through the guiding cylinder, further, the quantity, temperature, and pressure of the "transportation wind," the distance of the spray nozzle from the surface to be coated, etc.

It is well known that with the oxyacetylene blow pipe and with the electric arc temperatures of 2500 deg. or over may be

FIG. 1.—PRINCIPLE OF METAL SPRAY APPARATUS

produced. The application of this process involves neither theoretical nor practical difficulties in the production of coatings of brass, copper, nickel, iron, gold, and even platinum, and it permits the production of beautiful coatings free from oxide on any surface whatsoever. The italics are used with purpose to avoid any misunderstanding and to indicate that even inflammable substances, like wood, paper, celluloid, woven fabrics, and even explosives can be coated by this process. As an example, it may be said that a bunch of safety matches taken from its box and brought without any further preparation into a spray of brass was covered within two minutes on all sides with a brass coating without the heads of the matches being ignited.

Fabrics of every kind, including fine Brussels laces, can be coated with copper after they have been spread on a board. The Army department of a large country makes experiments at present with balloon material which we coated in Zürich on one side with a brass film of 0.002 millimeter (0.08 mil.) thickness.

The surprising fact that inflammable or fusible materials can be coated by this new process is probably explained by the considerable reduction of the temperature of the very finely divided particles caused by the sudden expansion of the com-

FIG. 2.—PRINCIPLE OF MODIFIED METAL SPRAY APPARATUS

pressed air in the moment of spraying. Moreover, the first thin film formed acts later on as a protecting layer.

I do not intend to discuss the theory of the process any further, but one fundamental difference between this new process and the older process using metallic powder may be pointed out. In the new process, the temperature of the blow lamp flame is hardly much different from the melting point of the metal, since the spray takes place immediately after melting. On the other hand, in the old process in which metallic powder

was used, the spray coming out of the spray nozzle consists of an intimate mixture of metallic powder and air or gas and each metallic particle is surrounded by an insulating film of air which is, of course, highly heated so that the heat efficiency is necessarily reduced.

Other advantages of the new process are that there are no more losses of metal and that the blow lamp can be easily adjusted so that the melting and spraying process takes place in the reducing zone of the flame.

Fig. 3 is a photograph of a "metal spray pistol" which is based on the new principle. Its design is the outcome of experiments, which were continually carried out for more than a year and a half in which my associate of many years, Mr. F. Herkenrath, participated. *a* is the wire of the metal to be sprayed; *b* are two guide rolls which are geared to the compressed air turbine *c*. By means of the handle *d* the supply of the gas as well as of the compressed air is cut off.

The compressed air supplied to the apparatus first sets the small turbine *c* in motion (30,000 to 35,000 revolutions per minute) by means of which the wire is pushed with an adjustable and uniform speed into the spray nozzle. From the turbine the compressed air passes in form of a concentric cylinder to the opening of the spray nozzle and aids the blow flame in subdividing and spraying the metal.

When certain metals like iron and copper are sprayed there is a clearly discernible smell of ozone. We have not yet found a certain explanation of its formation.

Fig. 4 shows the use of the metal spray pistol in practical operation. It is suitable for making coatings of brass, copper,

FIG. 3.—METAL SPRAY PISTOL

steel, etc., and is operated with hydrogen, oxygen, and compressed air. The box on the floor contains the coils of wire.

The metal spray pistol is particularly suitable in all cases where complicated surfaces or surfaces with large dimensions and in a somewhat remote position are to be coated. For instance, it is only a question of time when ships of the navy and of the mercantile marine will be coated with an adherent layer of copper. Experts consider the solution of this problem to be of eminent importance for the whole ship building industry and a practical solution of this problem has been sought as long as ships have been in existence.

Radiators for heating houses when coated with brass look good and also have a better heating efficiency than radiators coated as usual with a heat-insulating paint. In the electrical industry the process is suitable for many different purposes, as in the manufacture of resistors of all kinds, for making carbon conductive, for coating contact points in order to reduce the resistance, etc.

The many fields in which the process can be used and will be used, might best be illustrated by enumerating some of the things which have been sent to me in the course of time to Zürich to experiment with. It is a real museum which has nothing to compare with and which comprises brass-coated doll heads, sharpnail igniters, balloon material, metallized paper for transatlantic transportation, machine parts coated inside with

zinc or lead, beer kegs coated with tin, linen screens coated with aluminium for moving picture shows, cables coated with zinc, art products in which the metallic coating produces a special decorative effect, etc. It is no exaggeration to say

The Technical Analysis of Ferrovandium and Its Products

The Determination of Aluminium in Ferrovandium

By Wm. W. Clark

The writer will give a series of articles on the determination of the different constituents of ferrovanadium and its allied products. The methods given are in daily use, and have proven accurate, and rapid enough for routine work.

The determination of aluminium in ferrovanadium is the first, the method given having been in use for about three years. It is fairly rapid in comparison with other aluminium determinations, taking about 3 hours for a single determination, while a single operator will run 12 in an 8-hour day.

A number of methods were taken up and discarded, those that at first sight looked the best adapted for the material being given with the objection to it.

The precipitation of the aluminium from the neutral or acetic acid solution as phosphate with thiosulphate of sodium, and the precipitation with organic precipitants were discarded as useless, as vanadium precipitated with the aluminium in each case and under all conditions. The precipitation of the iron with sodium hydrate, and the determination of the aluminium in the filtrate is a long, tedious operation. The iron forms a very bulky precipitate, from which the aluminium is separated with difficulty, taking several reprecipitations, and a large bulk of wash water. The method while accurate takes about 12 hours for a single determination.

The fusion of the alloy with sodium peroxide, and the determination of the aluminium in an aliquot portion of the filtered solution, gives low results, as some aluminium is always held out of solution by absorption in the iron precipitate, and consequently an accurately measured part of the aluminium is not taken with the aliquot portion.

The method finally accepted as being accurate under all conditions, and rapid enough for a busy laboratory is as follows.

Dissolve 0.50 grams of the finely powdered material in 30 cc. strong hydrochloric acid and 5 cc. strong nitric acid, evaporate to a skim, add 20 cc. strong hydrochloric acid, transfer to a separatory funnel, washing out the beaker with a small amount of dilute hydrochloric acid (2 parts acid to 1 part water). Add 75 cc. ether, cork, and shake for 2 minutes. Allow the two layers to separate, and draw off the lower portion into a 400 cc. beaker, being careful to get the drainings from the sides of the funnel. Evaporate the dissolved ether, being careful not to ignite it, add 1 gram sodium chlorate, boil 1 minute, dilute to about 300 cc. with boiling water, and add sufficient excess of sodium hydrate solution to insure all vanadium and aluminium passing into solution. Add bromine if nickel is present until the precipitate turns black, boil 2 minutes, then add 25 cc. hydrogen peroxide, boil 2 minutes, and filter on a close filter using a platinum cone to prevent the paper from breaking, and washing the precipitate with hot water. Boil the filtrate and if any precipitate forms filter again on a close hard filter. Acidify the filtrate with dilute hydrochloric acid, add 25 cc. hydrogen peroxide, then ammonia until the solution just smells faintly of it, dilute to about 800 cc., and boil until the solution no longer smells of ammonia. Filter on a loose filter washing the precipitate with hot water until the washings are free from chlorides, ignite in a weighed platinum crucible at a low heat, finally blasting for a few minutes. Cool, add a few drops of sulphuric acid, 10 cc. of hydrofluoric acid and evaporate to dryness to remove any silica and ignite over a blast lamp until all sulphates are decomposed. Weigh and subtract from this weight any blank of alumina in the reagents. The resulting weight of Al_2O_3 multiplied by 106.60 gives the percentage of aluminium in the alloy.

The upper layer of ether left in the separatory funnel is distilled in an electric still, the ether vapor condensed and used again with very little loss.

The silica could be removed from the solution at the start by evaporation to dryness with hydrochloric acid, and subsequent solution in hydrochloric acid, and filtering, but a number of

FIG. 4.—APPLICATION OF METAL SPRAY PISTOL.

that every second day something new comes up, although it is also true that the inquiries received are often senseless and that valuable suggestions of new and useful applications of the process are the exception rather than the rule.

Zürich-Höngg,
Switzerland.

The metallurgical sources of gold recovery in 1911, according to figures just given out by the United States Geological Survey, were as follows: Dredging, 10.0 per cent; other placer operations, 13.1 per cent; amalgamation, 23.0 per cent; cyanidation, 26.1 per cent; chlorination, 3.8 per cent; smelting, 22 per cent. These proportions probably will not change greatly for 1912, although the recovery by chlorination may be entirely eliminated, and the recovery by cyanidation may increase. Dredging also will increase its output.

The filtration of finely divided precipitate may be accomplished by the aid of a thin film of collodion, according to Zsigmondy, Wilke-Dorfmüt and Galecke, in the *Berichte*. To prepare these films a 6 per cent collodion solution is diluted with twice its volume of ether and five times its volume of absolute alcohol, and poured in a thin film over a glass plate. When the ether has evaporated so that the collodion is no longer sticky the plate is plunged into water. After 10 or 15 minutes the film can be separated from the glass, and can be preserved under water. To prepare the filter, first place an ordinary ashless filter paper on the filter-funnel, and then cover the paper with a piece of the collodion film. See that the film covers the paper and is pressed against the sides of the glass funnel. Use in the usual way with a water-jet pump.

tests have shown that the removal of the silica in the crucible by means of hydrofluoric acid, gives the same results, saves considerable time, and removes any blank of silica from the reagents.

The lower portion drawn off from the separatory funnel should be a deep blue or green color, and if brown, as it sometimes is from the presence of nitric acid, must be evaporated again with hydrochloric acid, and the ether separation repeated with fresh ether.

The precipitate from the soda precipitation is small, allowing the aluminium to be washed out very easily. It contains all the nickel, manganese, and a small portion of the iron. The bromine is first added in this precipitation to make the precipitate of nickel granular, thus saving considerable time filtering, and the peroxide is added later to precipitate any manganese in the solution. The nickel can be determined from this precipitate, by dissolving it in hydrochloric acid, precipitating the iron with ammonia, and determining the nickel in the filtrate by titration with silver nitrate and potassium cyanide.

When oxidizing with hydrogen peroxide in the final precipitation an excess must be used, as this is the main point of the method. Vanadium will precipitate with the aluminium turning it a light yellow, if the peroxide is not in excess. This yellow color can be removed by adding more peroxide and ammonia and again boiling. The precipitate of aluminium hydroxide filters very rapidly, and will contain no vanadium when washed free from chlorides with hot water.

If the alloy contains an appreciable amount of phosphorus, the solution in the platinum crucible, after removal of the hydrofluoric acid, is diluted, sodium ammonium phosphate solution added, and the aluminium precipitated from the almost neutralized solution with sodium thiosulphate, filtered, washed, ignited at a low temperature in a porcelain crucible, and weighed as $AlPO_4$, which, after the subtraction of the blank, is multiplied by 44.38, giving the percentage of the aluminium in the alloy direct.

Following are some results on a synthetic solution of the approximate analysis of the ferrovanadium solution to which a known amount of aluminium was added in the form of aluminium potassium sulphate, and on a standard ferrovanadium.

Synthetic solution		Standard Ferrovanadium

American Vanadium Co.,
Bridgeville, Pa.

The only important manufacturer of pig iron in Mexico is the Cia. Fundidora de Hierro y Acero, of Monterey, Nuevo Leon. In 1911 this company produced 71,337 tons of pig iron, being an increase over 1910 of 26,246 tons. Imports of iron into Mexico during the fiscal year 1910-11 were made from Great Britain, United States, Germany and China. The duty assessed on foreign pig iron by the Mexican government is 0.02 peso per gross kilo, equivalent to about 0.45 cent per avoirdupois pound; on wrought iron and steel in ingots, 2.5 pesos per 100 gross kilos, or about 0.56 cent per pound. In addition to this duty a surtax of 5 per cent is assessable under the provisions of the budget of June 3, 1912.

The price of standard topographic maps issued by the United States Geological Survey was increased on January 1 from 5 cents each to 10 cents each, wholesale lots being sold at 6 cents when the order amounts to \$3 or more.

The Manufacture of Chilled Iron Car Wheels

A New Titanium-Boron Ferro-Alloy and an Apparatus for Testing Car Wheels

By Dr. Frederick C. Weber

In making a plain chilled iron car wheel from the usual mixture of pig iron, generally foundry No. 3, old car wheels, and steel and malleable iron scrap, there are always a small number of wheels which are found to be of very inferior quality, when subjected to testing and inspection.

A wheel should stand a thermal test of not less than two minutes before cracking. The drop test of dropping a weight onto the wheel is practically worthless, for there is no strain on the wheel flange during service which is similar to this drop test strain. The flange test should be a direct pressure strain on the flange and should show a direct resistance directly proportional to the weight of the car wheel and the load it is intended to carry.

No standards embodying the above are established yet. How many tons of strain there are on the flange of a wheel in service is variable. It depends on the velocity of the train, the degree of the track's curve, the width of the gaps at the rail joints and at the frogs and crossings, and on the way the car is loaded.

When making direct pressure flange tests the loaded car load weight is to be subtracted from the direct pressure breaking strain or this strain is to be compensated for by adjusting a vertical pressure for each weight car wheel. This can be done in a flange testing machine, of suitable construction.

The above factors collectively determine how much strength must be possessed by a wheel flange to be safe during service. I have arbitrarily placed the required strengths at the following figures based on such data as I have been able to gather. There are four car wheels which can be considered as being standard sizes, having a weight of 625, 675, 725 and 800 pounds respectively. The thickness of the flanges is proportional to the wheel's weight or better, proportional to the car load strain. The first weight is that of a wheel for cars carrying loads up to 30 tons, the second for cars carrying 30 to 40 tons, the third for cars carrying 40 to 50 tons, and the fourth for extra heavy cars of 50 tons capacity and over.

The breaking flange strengths should be taken irrespective of the varying load bearing upon the tread of the wheel. The first wheel should have a minimum flange strength before breaking of not less than 55 tons, the second of 65 tons, the third of 75 tons, the fourth of 85 tons. All of these strengths should be for between the brackets. For over the brackets the strengths should be 5 tons higher in each case.

The testing machine must be adjusted to exert a vertical load pressure of 12, 15, 18 and 20 tons on the several weight wheels to represent the loaded car pressure on the tread. And the flanges must show the above resistances for flange strengths before breaking with these load pressures bearing on the tread of the tested wheel. All wheels should, of course, average higher for all weights for all lots.

The above figures for strengths are purely arbitrary, but reasonable and fair and can be met in all foundry practice now. These figures should be the minimum for wheels to pass inspection.

Car wheels which are made from the above mentioned mixture will stand a flange test as above, all the way from 35 tons to 60 tons for test lot averages, and as high as 90 or even 100 tons for an occasional wheel. But quite a number creep in which are as low as 25 tons. It is this marked unevenness which is the most serious feature of a chilled iron car wheel. It is the low test wheel which gives out in service and which it is the aim to eliminate.

Under a freight car using a four-wheel truck there is a distribution of weight per wheel of practically one-eighth of the car's weight loaded or unloaded. In railroad operating practice this figures out as there being practically one-third of the total weight for the empty cars when figuring loaded train

weights. It gives a down pressure of practically 20 tons per wheel due to jolting on the tread of the wheel for the standard unit 50-ton loaded freight car, for the smaller cars less.

The factors to consider when calculating strengths required for flanges are as given above plus the centrifugal force in rounding curves and the pounding of the wheels over the gaps in the rails at the rail joints and frogs and crossings.

Iron which is of low grade and of uneven composition is more or less weak at all times. It is this uneven iron which causes so wide a range in the wheel's strength. Then there are the brown spot flaws in the throat between the tread and the flange which when present means a broken wheel every time in service.

This brown spot flaw I consider to be an incipient check due to viscosity of the molten iron at the time of pouring and it not filling the mold solidly. This incipient check at the moment of forming becomes oxidized to Fe_2O_3 because the iron is red hot. During service of the wheel the check becomes enlarged to a well defined crack and this enlargement becomes covered with Fe_2O_3 .

Then the chilled iron car wheel is subject to the formation of what are technically known as "bones." These bones I consider to be of two distinct kinds. First, bones of a segregation of slags, and second, a bone of a hard spot of steel. This steel bone hard spot comes from the steel scrap fed into the cupola with the mixtures, and the steel not becoming fully melted and incorporated with the rest of the metal in the cupola. The segregation bones of slag get into the wheel by slag flowing through the spout of the pouring ladle and by the segregation of slags within the body of the metal.

These two bones can be avoided first by exercising care to keep the work in hand by keeping slag from flowing into the pouring ladles from the bull ladle and second by scavenging or rather cleansing the molten iron.

Here a change in foundry practice is clearly indicated. The bull ladle must not only be mounted on trunnions, but it must be so constructed that it can be emptied from below either by having a vertically placed skimmer or be tapped below so that no slag will flow into the pouring ladles from that on top of the metal in the bull ladle. There must be some slag floating on the molten metal to cover it in the ladles to prevent oxidation and nitrogen absorption, but in the pouring ladles a film at once forms acting as a protection and then the pouring ladles are soon emptied. That will eliminate the plain slag bone.

The other, the segregation slag bone, is perfectly eliminated by means of a ternary alloy of iron, titanium, and boron.

The steel hard spot bone must be kept out by using no scrap steel in large pieces and then the scrap must not be covered with dirt or clay which will form a crust over the scrap and prevent it from melting and mixing into the mass of metal in the cupola.

It is at the frogs and crossings where the bones play havoc, for the softer metal at the sides of the harder metal of the bones becomes crowded past the bones by the cold flow of the softer metal by the pounding and then it is only a question of time when the iron having become tired, breaks.

The strain on the flange varies through a wide range with the train in motion. The track is never dead level. When rounding curves the outer rail being higher equalizes some but the train speeds are never the same, so consequently the speedier the train the more pressure on the flange.

Then there is the factor of the temperature to consider, for instance, when the thermometer reaches 40 below zero with the attendant effect of making the iron cold short.

Making a chilled iron car wheel to meet these various requirements is not exactly a boy's job. The essentials are a tread and flange far harder than the rail to minimize abrasion and having a toughness needed to withstand the pressure produced by centrifugal force on the flange, in rounding and pounding around curves at all speeds and temperatures.

It can be done! The iron's composition and handling as influenced by the various processes to which it is subjected, are the factors which must be considered in making a wheel which is to meet the severe calls made upon it when in service.

The very first factor for improvement is to empty the bull ladle from below to eliminate the plain slag bone, and to neutralize in the pouring ladles any added cleansing or scavenging compounds or as the foundrymen say dope.

No steel or malleable scrap should be added to the mixture which is in any way dirty. As a matter of safety all steel or malleable scrap should be cleaned in a rattle-box first. This will surely eliminate the steel bone.

The coke and limestone and the pig iron used in the cupola must be analyzed so that the right amount and kind of limestone flux can be added to the mixture so as to make a silicate slag. To correct any thickness of the resulting slags from using old wheels of uncertain composition some fluorspar, usually about 1 per cent, must be added to the mixture along with the coke and limestone.

But now comes the vital determining factor of causing the iron to have the essential quality of a fine, even, live, homogeneous grain with no interference with the irons taking the chill and additionally having imparted that strength which goes with purer iron while making it more liquid in the pouring and through these absolutely to eliminate the brown spot flaw, the segregation bones, and so eliminate the low test wheel.

An alloy—or rather my alloy, for I was the first to make it—composed of iron, titanium, and boron imparts the above essential qualities. The alloy contains Fe74, Ti12, B8, AlSi, etc., 6 per cent. This alloy combines with the occluded nitrogen which produces brittleness, it being fluxed out. The boron fluxes out the slags from within the molten metal and incidentally brings up some phosphorus and sulphur. While the trifle of aluminium in the alloy reduces whatever oxides of iron and manganese may be in the iron which along with the slags in the iron makes the iron viscous or pasty.

A curious action of the boron is that at the temperature of molten iron the boron determines that some of the graphitic carbon enters into combination, it becoming combined carbon. While at the temperature of molten steel, all excess of boron over that required to flux out slags is converted to B_2C_3 and this acts to throw carbon out of combination, making it graphitic.

The iron treated with this alloy has a live appearance. Its color is of a lighter gray, finer grained. It is homogeneous throughout and the chill looks more fibrous and steely. During all testing of wheels treated with this alloy so far not a single brown spot flaw nor a bone has been found nor has a low test wheel appeared. None were found on flange testing as low as the minimum demanded, while a number were found breaking as high as 110 and 117 tons. And that for medium weight wheels No. 800 lb. wheels were made or tested.

To use this scavenging alloy means that the foundry methods and practice must be adapted to its requirements. The alloy being a fluxing alloy demands that it be thrown into the bottom of the pouring ladles, the ladles being red hot and empty or nearly so of the previously poured metal. The iron from the bull ladle flowing onto the alloy mixes it in and the fluxed out impurities of the treated metal rising to the surface promptly furnish the required protective film of slag.

The slags formed during melting the mixture and flowing from the cupola cover the molten metal in the bull ladle if they should flow from there into the pouring ladles and then come into contact with the cleansing alloy, they would at once flux between themselves and the alloy would be waste!

The alloy is not neutral to the slags like a metallic alloy, as for instance, ferrochromium. The cleansing alloy will flux out the impurities from the iron only when the iron and the alloy are in shape for the alloy to act on the impurities in the iron. The aim is to cleanse and scavenge the iron and not to flux any floating slags.

The alloy will when correctly used flux with the impurities of the iron into which it is incorporated up to its saturation point. Of course, the cleaner the iron the less alloy will be required to obtain a given result. But the very fact that it scavenges the molten iron by a true fluxing action means the production of a far more uniform iron.

All the way from $\frac{1}{2}$ lb. to 5 lb. per wheel were used. In some as little as $\frac{1}{2}$ lb. was required to show a good improvement in the iron. Even this small amount of the alloy eliminates the brown spot flaw.

Boron was found in the treated iron when 3 lb. and over per wheel was used. The 3 lb. per wheel were the strongest wheels.

It has been found in practice that the alloy must be thrown into the bottom of the pouring ladles in fine powder, not coarser than will pass a 12-mesh sieve. It dissolves very readily in the molten iron and is best thrown into the pouring ladles as fast as they are fully emptied from pouring a wheel. The alloy then has the necessary time for action from one pouring to the next.

The increased strength of the iron is that increase which is the result of its being cleaner, more homogeneous, and of finer, even grain, and the improvement is such that the cleansed metal is very decidedly better than non-cleansed metal. This alloy is the best scavenger so far used.

The testing of a wheel for its flange strength must be done with a proper regard to its being at least approximately correct. No such thing as putting a wheel into a frame and putting a hydraulic ram at the hub by guess at centering will show anything one way or another.

The frame must be a rectangle or a rhombus with its greater diameter placed horizontally. Its upper side must have an inserted vertical pressure block.

Sliding up and down in a rectangular orifice in this block's lower face there must be a recess accurately fitting the car

rod. This buffer block must be of sufficient thickness to stand up under the heavy pressures used. The block's faces must be in parallel planes.

The center of the interspaces between the brackets on the wheel must be correctly marked so as to enable placing and fastening directly over a mark on the frame and rail. And just so for over the brackets. The wheel must be fastened centrally over the piston of the hydraulic ram.

The vertical ram piston pressing on the vertical pressure block which represents the car's weight can be accurately adjusted to the several weight wheels by forcing the ram piston a little beyond the required pressure and then by means of a fine thread opening drip cock drawing off enough of the liquid as will make the needle show the desired pressure.

In this way only can wheels be tested so that the tests are of any value. And incidentally this avoids the guesswork method of centering the buffer block and so prevent slipping one over on a too confiding unsuspecting inspector by changing the leverage to get a resulting low or high test at pleasure.

There are a number of details connected with this work. The centering rod must be removed as soon as the wheel is firmly held in place by the buffer block so that the wheel hangs free while the pressure is applied.

Then a washer of soft sheet iron or of annealed sheet aluminum can be placed between the piston faces and the blocks so as to compensate for any being out of line. The pressure on the vertical piston will be up to 2000 lb. per in. for a 6-in. piston and up to 3000 lb. on a 14-in. horizontal piston, when flange testing.

These pistons are best connected to one force pump by a proper system of double extra strong pipes with valves so inserted that the pressure is first put on the vertical pressure block and adjusted to the weight of wheel undergoing test. The pressure at 2000 lb. can be run up to 28 tons if desired. The pressure is then turned onto the horizontal breaking piston.

The pump is calculated for a working pressure of 3000 lb. which for the 14-in. piston gives an effective pressure of 230 tons for a direct acting breaking strain. This is more than three times the strain on a wheel flange in service and more than double the strain called for to pass a wheel by inspection.

A chain hoist on a traveler can be rigged up to handle the wheel for placing in position in the testing machine. And a pinch bar comes in handy for adjusting to guide marks.

wheel's flange and tread accurately tangent throughout an arc the chord of which must extend back for $\frac{1}{4}$ in. onto the tread for additional resistance.

The opposite lower side must be a rail or a rail head on which the wheel rests. This rail must be reinforced at the head for greater resistance. In this manner the wheel being free horizontally, the pressure is exerted on the flange in a similar manner by pressing on the rail head as obtains with the wheel in service. A wheel to make a flange test must have the central orifice centrally reamed out at right angles to the plane of the wheel. The hub must be smoothed up by planing or turning on a lathe accurately at right angles to the central orifice.

An iron or better, a steel rod, must be put into this central orifice which will just allow of its easy introduction and withdrawal. This rod must be tapering at the end for about an inch and the taper must project so that a buffer block can be placed over the taper between the hub of the wheel and the piston of a hydraulic ram. This accurately centers the buffer block over the hub of the to be tested wheel.

This buffer block must also be turned in a lathe so as to be round and true and be just large enough to cover the hub. It must have a recess made accurately to fit over the taper of the

Pennsylvania far outranks all other states in the value of its mineral output. In 1911 this state contributed, exclusive of pig iron, 24.7 per cent of the total mineral output of the United States. The reason for Pennsylvania's undisputed leadership lies primarily, according to the United States Geological Survey, in its great production of coal. It is almost exclusively the source of anthracite, and produces over one-third of the total bituminous output. Pennsylvania ranks second, next to New York, in the value of its manufactures, and stands first as a producer of cement, coal, coke, pig iron, lime, mineral paints, sand and gravel.

Tungsten is used chiefly in making steels that will hold their temper when heated, but it is more generally known as supplying the filament of incandescent lamps. Diamonds are used for drawing tungsten wire for the latter purpose, and wire of 0.0006 in. in diameter is now drawn in quantity. New uses are being found for tungsten in making electric contacts and targets for Roentgen rays.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in October, 1912, was 62. The total quantity of ore milled during that period was 2,252,040 tons. There were 9,075 stamps in operation, with an average duty of 8.56 tons per 24 hours. Tube mills in commission numbered 281. The yield for the month was 768.681 fine ounces gold, being about 60,000 ounces more than during the same period of 1911. The yield per ton milled was 6.64 dwts.

Organization

An Outline of Essentials from Engineering Practice

By T. C. Roberts

ORGANIZATION is one of the problems that all executives feel that they are thoroughly familiar with. They feel that their organization is laid out on exact scientific lines. They feel that if they are not getting the results they would like to get that it is not due to any fault of their method of organization, but due to some individual weak link in the chain in the form of a personal factor, and in a great many cases they are right.

There are numerous books written on the subject of organization, and it has been widely discussed, but 99 per cent of the friction or dissatisfaction in your organization is due to your lack of proper organizing ability. You who read this will probably say that it does not apply to your organization, because you have no friction or dissatisfaction among your men. But, let me tell you that you have. It may be, and probably will be, with your best men a carefully guarded secret, and one that they would be very reticent about divulging or discussing, even if approached upon the subject. It is

there just the same. Sometimes it is due to some one man in the organization, who may have reason to feel that he is abused, discriminated against, not allowed to advance according to his ability, etc., and sometimes he is right.

It is a fact probably based on the old adage that "familiarity breeds contempt," that a great many—I am even going to say that most executives—fail to appreciate the ability of their own men. Each and every one of us can verify the truth of this statement by reviewing our own experiences, and no doubt remembering some instance where we were pushed aside to make room for some one who had no greater ability than we had; and we could see what those higher up probably did not see; and that was, that the fellow who supplanted us received a considerable part of his experience after he got on the job. He probably, though, was a man of considerable ability and would

soon be able to introduce new and better methods into the organization, and if we will be absolutely fair in our reminiscences we will probably be able to recall some fellow whose place we took, who, if given the same support that we were accorded, would have been a better man than we were, and who probably proved it in some other organization.

The mistake that is made the greatest number of times is one of not outlining each man's duties, and demanding that everybody keep on their own side of the line. How often do you go to some man in an organization and ask him who has charge of certain work, and receive the answer that "if things were as they should be that he would have charge of that work, but as it is some one else has charge of it." Now, Mr. Manager, there is something for you to think about. That man is in one of several classes, and that answer was prompted from one of several causes. It was a case that was probably never brought to your attention. It might have been the only time

FIG. 1.—ORGANIZATION CHART SHOWING BUSINESS PASSING TO DEPARTMENT HEADS THROUGH ASSISTANTS

that that particular man ever gave utterance to what he really felt, yet how could you know that the feeling existed? I will tell you how. If you are a competent organizer you will be able to figuratively put yourself in the place of every man in your organization, and will analyze what your feelings would be if the system were applied to you.

A great many times your system is too flexible, and it would do you good to make an organization chart showing how many paths a report could take in getting to you. In other words, how many chances the man below has to get around the man above. And, how many times you offended some foreman by going around him to some man below, thereby licensing things to get out of their right channel, and making it possible for a weak character to tell somebody, in strict confidence, that when the "Old Man" wants to really know anything about the work-

ing of things he ignores those above and comes directly to him. Which remark, made in the strictest confidence, gets back to the man in the middle, who immediately and rightly gets peevish with you and the man below.

New blood in an organization brings new ideas, and a great many times new improvements, because the new man in trying to familiarize himself with the conditions sees a chance for improvement. While the new men may bring in new ideas, the

Another method, and I believe the most successful one, is to carefully define the duties of every foreman or superintendent, and where there is a chance of the duties of one department to overlap another the line should be very carefully drawn. This, you may say, is impossible, but it is not. By giving careful attention to the matter, you will find a point where the line can be drawn with satisfaction to all parties concerned. Do not assume that any two men will work in harmony in a case of this

kind, because they will not. If a man is ambitious to make a record that will some day land him in a higher position, it is human nature, when opportunity presents, to show the management how much he knows about the other fellow's job.

In other words, we all try to show that we are fitted to handle anything that is offered, and it is this very thing that will forever keep "Damon and Pythias" brotherly love out of the business organization. And, you can not blame any one of a dozen foremen in a large organization, and who are on an equal basis as far as salary and importance of position are concerned, for endeavoring to show the management that he is better fitted to fill a superior position than any one of the other foremen in his class. And, if in calling attention to his ability he gets on the other fellow's territory you can not expect the other fellow, who is equally ambitious, to not retaliate in kind, and there is a condition to watch.

One of the hardest conditions to meet is the impatience of men to wait a long time for promotion, and it occasionally creates trouble, because men striving for recognition and success in the line that they are engaged in are not prone to sit down contentedly and wait for a vacancy to occur, but they are liable to call attention to the other fellow's failings in the same breath in which they sing their own praise.

A properly arranged organization chart, showing the line of succession, will do as much toward keeping the business in its proper channel as any other one thing, and these charts can be posted throughout the works so that no man would have an excuse of ignorance for going out of the proper channel, except in case of emergency. Also a chart should be drawn in lines of

two different kinds, one showing the course to take normally, and the other showing the course to take in case the proper channel is closed.

Some managers prefer to have all reports from the works come up in line of succession through their assistants, as shown in Fig. 1, and some prefer to have the reports come direct to them, and they then assign to their immediate assistants the work that each one is to check (Fig. 2). It takes only a few minutes' time to lay out such charts and they are very valuable, as has been proven by experience. Continuous lines show path to be used under normal conditions, dotted lines show path used in cases of emergency.

In addition to the general chart, each department should have

FIG. 2—ORGANIZATION CHART SHOWING ASSISTANT DEPARTMENT HEADS ACTING ONLY ON CONSULTATION WITH DEPARTMENT HEADS

old men in charge of various departments, by taking an occasional trip through other plants, would be just as quick to see and bring back ideas that would more than pay for the expense of the trip.

Different managers use different methods in keeping in touch with what is going on. Some do not believe in giving too much authority or putting too much confidence in any one man, and adopt the theory that if they want to know what is going on in one foreman's department that they should ask the foreman of some other department to make them a report on the other fellow's work, and yet this class of managers think they know all about maintaining harmony and satisfaction in an organization.

a detail chart showing the department lineup. Try it and see what results you get. You will probably find several men will offer in explanation of their actions in the past regarding certain things, that they did not know that they were supposed to take such matters up in the manner outlined on the chart. You will probably be surprised to find out how little each man knows of what your intentions really are in your system of organization.

I recently read an article in a technical magazine on the subject of organization. Also, the editor's comments on the same. Both the author and the editor seemed to be offering a solution for a difficulty that had arisen in a certain organization, due to the difference in training between an operating and a construction engineer. They seemed to feel that there was such a great difference that they would not be able to agree on any subject pertaining to their work, and therefore should be kept entirely separate, and each one report separately to the president of the company.

This division often confronts the manager of a large organization. But, to the man who is in close touch with the situation, the solution is apparent. The men in the operating department have probably for several years been operating their plant more or less successfully. If any difficulty has developed they have solved the matter in a manner satisfactory to themselves. They know the weak spots in their equipment, and what should be done to strengthen them. Working along these lines the time comes to install new equipment. The engineering department is consulted, through the chief engineer. Plans should be worked up, in consultation with the operating department; the designing engineer, the operating engineer, and the construction engineer working together under the supervision of the company's chief engineer.

When the plans are out, material purchased and delivered, the actual work of installing the plant should be under the direction of the construction engineer, who has outlined his method of procedure by familiarizing himself, in consultation with the operating engineer, with the conditions in the operating department effected by the construction work. But, both of these men should be under the supervision of, and report to, the chief engineer, the chief engineer in turn making his report to the manager or president.

It is absolute folly to argue that operating engineering and construction engineering should be divided into two departments, each one working absolutely independent of the other, and each one reporting to the president, as suggested in the article mentioned above. In a great many cases the president or manager, as the case may be, is not familiar with the dividing line between the operating and construction engineering. Therefore, both these departments, along with all other engineering work of any nature, should be under the supervision of, or referred to the chief engineer.

If more managers would realize this fact there would be less costly experimental work and time lost by the head of some department trying to work out some pet scheme of his own, without the aid of the engineering department. I have known of various organizations where the foremen or superintendents of the various departments, for fear that they would not get credit for ideas originating with themselves, have worked out their own engineering problems, which is entirely wrong if the organization is maintaining an engineering department.

The engineering department, through the chief engineer, should be directly responsible to the manager of the organization, and all matters going into or out of the engineering department should pass through the manager, or his immediate assistants. I am familiar with one mining and milling organization whose policy it was to keep each division of engineering separate. That is, they had a chief mechanical engineer, a chief civil engineer, a chief electrical engineer, and a chief hydraulic engineer. Each branch had its own assistant engineers, draughtsmen, clerks, etc. Each chief engineer was reporting directly to the general manager. They were in a constant turmoil. If there was a piece of work to design affecting more or less all of them, each department would design a propo-

sition as they thought it should be. Each one holding out for his particular design, with a consequent delay, and a hybrid creation when the job was finished.

This condition prevailed in this organization, which was no small affair, until some one suggested the appointment of a general chief engineer, and while it was true that the chief engineer of each department felt that he should be appointed as the general chief engineer, yet when the company appointed a man from outside the organization, they all fell into line, the engineering departments were consolidated with each of the original chief engineers as the head of a department of their particular line of work.

Two other organizations that I am familiar with, one the American Smelting and Refining Company, and the other H. M. Byllesby & Company, one a mining, milling and smelting company, the other an engineering, holding and operating company are laid on very similar, and along the lines that outline each man's duties and I would like to see, in the interest of scientific organizations, a complete organization chart of each of these companies published, but I am satisfied that any one sufficiently interested could obtain a general outline of the plan of organization by communicating with these companies.

It is true, however, that in lining up your organization you will probably find some one in the organization whose ideas differ from your own, but that person should, as Hubbard says, "Get out or get in line," and unless every person in the organization will try to make the system as outlined a success, whether it is in accordance with their views on the subject or not, they are an undesirable factor in the organization, and should be eliminated.

Note on the Calibration of Optical Pyrometers

By Paul D. Foote

In the primary calibration of all forms of optical pyrometers it is necessary to sight upon a substance in which the temperature distribution is such as to obtain "black body" conditions. The Lummer and Kurlbaum electrically heated black body is in general use for this purpose. As modified by Wadner & Burgess¹ by the introduction of a supplementary heating coil at each end, very uniform temperatures may be maintained over a short length of the furnace. However, it is only after the most careful adjustment of diaphragms and the auxiliary heating circuit that platinum and carbon placed inside the "black body" become indistinguishable.

If the walls are very much hotter than the back diaphragm upon which the couples are mounted and the pyrometer sighted light will be reflected from the diaphragm, and an apparent temperature higher than the true temperature is observed. On the other hand, a large temperature gradient through the furnace may lower the emission so that the thermocouples indicate a temperature higher than that shown by an optical pyrometer.

A method has been suggested² which eliminates the rather complicated and expensive apparatus necessary for the Lummer-Kurlbaum "black body." The optical pyrometer is sighted on the bottom of a porcelain tube, preferably blackened inside, the tube being thrust in a crucible of molten metal at the freezing point.

Dr. C. W. Kanolt³ has applied this method to the calibration of the Morse pyrometer (and Holborn-Kurlbaum type of that pyrometer) by sighting upon a small carbon tube projecting into a pot containing about 100 grams of molten metal. This was placed in an Arsem vacuum furnace and the freeze or melt observed through the glass window of the furnace.

By slightly modifying the above methods, a simple and inexpensive "black body," which may be constructed without dif-

¹Bureau of Standards Reprint No. 55, p. 165.

²Burgess and LeChatelier. The Measurement of High Temperatures, 3rd ed., Wiley, 1912, p. 332.

³Bureau of Standards Technologic Papers, No. 10, p. 8.

facility in the shops of any industrial plant, has proved highly satisfactory for work at the Bureau of Standards.

A large graphite crucible E, Figure 1, was made, capable of holding 1000 to 1500 grams of metal, D. The graphite cover containing the cylindrical "black body" B, was turned on a lathe and a conical hole drilled through, making an opening of about 0.5 cm. at C. In this manner the radiation coming from the black body passed into the pyrometer and none was intercepted by the graphite walls, the dotted lines, H, representing the cone of rays required by the optical system of the Holborn-Kurlbaum pyrometer. Over the metal was placed a layer of powdered graphite, G, in order to prevent oxidation.

A stirring rod, A, could be used to insure a uniform temperature through the pot, although the high conductivity of the metal probably makes this unnecessary.

The pot was heated in an electric furnace constructed by winding nichrome or platinum ribbon upon a porcelain cylinder 8 x 35 cm. However, if due care is taken to pack the crucible in a bed of powdered graphite, and some protection is afforded against the stream of oxidizing air, a simple gas furnace will serve very satisfactorily. Pots which have been in use twenty or thirty hours as yet show little sign of crumbling.

As a practical test of blackness, it is interesting to note that the opening, C, was indistinguishable and the only means of superposing the lamp filament and the image of the opening was by allowing a few drops of water to fall into B when for a moment C would appear as a dark spot in the field. Melts or freezes running

from fifteen minutes to an hour are easily obtained with antimony, silver, copper and other metals. A typical freeze for antimony is shown in Fig. 2. The flat part of the curve at once shows the current through the pyrometer lamp corresponding to the freezing temperature of antimony (630 deg. C.). By the use of the melts of three metals, the parabolic empirical relation $i = a + bt + ct^2$ may be established.

FIG. 2—TYPICAL FREEZING CURVE

If an observation at 1200 deg. C. is desired, inasmuch as there is no metal known to have a melt at this temperature, copper may be superheated and its temperature measured by means of thermocouples immersed in the liquid. However, when observations are made upon copper (1083 deg. C.), copper-silver eutectic (770 deg. C.), and antimony (630 deg. C.), the curve extrapolated as far as 1200 deg. C. reads identically with values obtained on the Lummer-Kurlbaum furnace at that temperature, and even as high as 1400 deg. C, the divergence between the extrapolated curve and the values actually observed is less than 1 deg., an amount of minor importance in industrial work. For higher temperatures an absorption glass should be used both on account of the inadvisability of

extrapolation over so great a range and for the safety of the pyrometer lamp, the filament of which begins to deteriorate, slightly, in this region.

Meyer¹ has suggested the use of an equation of the form $i = aT^n$ for the calibration of pyrometer lamps, where a and n are observed constants and T is the absolute temperature. This assumes² the filament to be of such a length that the thermal conduction along it is negligible. Both equations have been tried for several pyrometer lamps of the Bureau of Standards, and the parabolic form seems to fit the observations much more closely than the exponential equation. The latter form, however, possesses a distinct advantage in that only two points are required for calibration, but when used, it is necessary to know that the amount of heat dissipated by conduction along the leads is small in comparison with the total energy required by the lamp.

While the method of calibrating pyrometers by means of melts of certain metals as described above, is particularly intended for the Holborn-Kurlbaum pyrometer, it may be used just as satisfactorily with any form of optical pyrometer, care being taken that the cone of rays coming from the opening of the "black body" is not intercepted by the wall of the conical tube, and that the aperture is large enough to completely fill the optical system of the instrument.

Bureau of Standards.

Washington, D. C.

Effect of Heat on Amalgamating and Concentrating in Cyanide Solution

The use of warm solutions in cyaniding gold and silver ores, more particularly the latter, is no longer an innovation. Data on the practice are not as numerous as could be desired, but several instances are recorded in which warm solutions favorably affected extraction and settling. In some cases, perhaps, the results have shown little if any improvement over the use of solutions at normal temperature. This has been true of some silver cyanide mills of Mexico. Opposed to this, however, is the experience in silver cyaniding at Tonopah³, where solutions at 90 deg. F. materially increased extraction. In South Africa⁴ solutions are heated to temperatures ranging from 90 deg. to 120 deg. F., with beneficial effect on settling and a consequent increase of 20 per cent in tonnage treated. Other instances⁵ of the use of warm solutions can be found in the practice at the Hudson and Ophir mills, Colorado. Perhaps the most that can be said of the practice is that, in some instances, warm solutions are beneficial, whereas in others only negative results have been obtained.

Through the courtesy of the Liberty Bell Gold Mining Company, Telluride, Colo., we are able to present some interesting data regarding the effect of cold and warm solutions, particularly referring to amalgamation in cyanide solution. Metallurgical practice at the Liberty Bell mill⁶ includes stamping in cyanide solution, with subsequent amalgamation after both stamps and tube mills. Prior to April, 1912, cyanide solution was used at ordinary temperature, say 60 deg. F. Beginning with April, 1912, there was a marked increment in solution temperature, and a notable increase in percentage extraction of silver. The natural assumption was that the increased saving was due to better cyanide extraction. But upon tabulating the percentage recoveries from the different mill departments, some unexpected figures were obtained, which did not wholly confirm the first assumption. The following table gives typical percentages of recovery in the different departments over a period of one year, with an opportunity to compare the results obtained during the first half of that time, when cold solutions were used, with those of the last half when the solutions were warm.

⁶Notes on the Liberty Bell Mine, C. A. Chase, Bull. 60, A.I.M.E.

A marked gain is seen in total silver recovery, amounting to 10.57 per cent. Forty per cent of this gain, however, is by

Period.	Gold.				Silver.			
	Amal.	Cyan.	Conc.	Total.	Amal.	Cyan.	Conc.	Total.
First half.....	48.98	35.71	7.52	92.21	7.12	37.67	17.24	62.03
Second half.....	50.20	34.40	8.40	93.00	11.30	39.70	21.60	72.60
Gain second half.	1.22		0.88	0.79	4.18	2.03	4.36	10.57
Loss second half.	1.31							

amalgamation, and another 40 per cent by concentration, with only 20 per cent by cyanide.

Some laboratory tests were conducted to check the results obtained in the mill and to explain the distribution of the gain in silver recovery in the different departments. The following amalgamation tests with hot and cold pulp (barren solution) are suggestive.

Amalgamation Tests.

Test No.	Mg. Silver in Ore.	Mg. Silver Recovered in Amalgam.		Per Cent. Silver Extracted by Amalgamation.	
		Hot 85°.	Cold 60°.	Hot 85°.	Cold 60°.
1	61.8	2.18	2.90	3.5	4.7
2	"	3.41	1.65	5.7	2.7
3	"	5.50	2.95	8.9	4.8
4	"	2.68	1.58	4.3	2.5
5	"	5.93	3.46	9.6	5.6
6	"	4.22	3.94	6.8	6.4
7	"	6.86	2.90	11.2	4.7
8	"	9.62	3.16	15.5	5.1
9	"	4.80	2.60	7.8	4.2
10	"	7.96	4.47	12.8	7.2
11	"	8.20	4.50	13.2	7.3
12	"	8.16	3.70	13.2	6.0
13	"	5.42	4.35	8.7	7.0
14	"	5.59	5.62	9.0	9.0
Mean	61.8	5.86	3.42	9.45	5.52

The figures show nearly 90 per cent increase in amalgamation at a temperature of 85 deg. F. as compared with 60 deg. F. Similarly the following agitation tests in cyanide solution show an increased extraction of both gold and silver at the higher temperature, although the gain is not so marked in the case of gold as with silver.

Agitation Tests.

Ore assay: Au. 0.20; Ag. 2.06.		Temperature 85°		Temperature 60°				
Test No.	Tail Assay.		% Extraction.	Tail Assay.		% Extraction.		
	Au.	Ag.		Au.	Ag.			
1*	0.018	0.58	91.0	68.5	0.020	0.53	90.0	74.2
2	0.012	0.65	94.0	71.5	0.022	1.32	89.0	35.7
3	0.012	0.75	94.0	70.3	0.022	0.92	89.0	55.2
4	0.012	0.65	94.9	72.7	0.022	0.72	89.0	65.0

*Temperature on this cold test may have exceeded 60°.

It will be noted from the above tabulated amalgamation tests that the increase in silver extraction with warm pulp is fairly consistent. The gold increase was more erratic. This led to the suspicion that silver was being precipitated on and amalgamated with the mercury after first being taken into solution by cyanide. To confirm this view the following amalgamation tests were then made, using only mercury and zinc-box head-solution, with no ore. The same quantities of mercury solution were used as in the preceding tests with ore and barren solution, and the test was conducted for the same length of time, with the following results:

Test No.	Mg. Silver Precipitated on and Amalgamated with Mercury.	
	Hot 85°	Cold 60°
1	3.54	1.10
2	4.20	0.80
3	3.46	0.86

The increase in silver precipitated on and amalgamated with the mercury in the case of the warm solution was 8.1 per cent of the dissolved silver in the solution.

The average silver recovery in mill amalgamation for the period October, 1911, to March, 1912, inclusive, when cold solutions were in use, was 7.00 per cent. The same average for the following six months with warm solutions was 11.30 per cent, showing a gain of 4.21 per cent. The average silver content of the mill ore during the latter period was 2.45 oz. per ton. The apparent increased silver recovery by amalgamation during this period was, therefore, 0.703 oz. per ton of ore treated.

The average quantity of dissolved silver in battery solution during the latter period was 0.207 oz. per ton solution. Assum-

ing five tons solution used in the batteries per ton of ore treated, and 8.1 per cent more of its dissolved silver to have been precipitated and amalgamated on the plates than during the preceding six months, the increased quantity amalgamated amounts to 0.1202 oz. per ton of ore, or an apparent increased silver extraction of 4.91 per cent.

The indications are, therefore, that the apparent increase in silver extraction by amalgamation during the last six months is in reality an increased recovery by cyanide, probably due, as shown by the accompanying agitation tests, to the increase in solution temperature. The total increase in silver recovery should, then, more properly be credited to cyaniding and concentration, including in the former item that increase which is shown in amalgamation.

The foregoing results seem to indicate that, at least in this instance, heating is beneficial, and that the processes of amalgamation cyaniding and concentration are materially improved when performed in warm solutions. The reason for the gain in silver recovery by concentration probably is explained by the effect of heat on the settling process.

The Present Status of the Induction Furnace The New Two-Phase Combination Furnace and Details of Lining Construction

In the *London Electrician* of December 13, Mr John Hårdén gives an interesting review of the present status of the induction furnace and of some recent advances in design and construction. From this article we extract the following information:

"Development in the past has been somewhat handicapped by the fact that certain of the distinctive types of induction furnaces have been controlled by different interests, and a step in the right direction has been achieved by a recent combination of these various interests, by which the exchange of information relating to results obtained in the European countries and in America is made easier, while, in addition, it becomes possible to make combined use of the good points of the various patented types in designing future furnaces.

"In Great Britain the induction furnace interests are in the hands of the Gröndal Kjellin Co. (Ltd.), of London, who now control the patents covering the Kjellin, Röchling-Rodenhauser and Frick types of furnace. The distinction between these three types is sufficiently well shown for the present purpose by Figs. 1 to 4.

"Neglecting those furnaces which have been erected from time to time for experimental purposes, there are now working, or under construction, nine Kjellin furnaces, with a total capacity of about 17 tons; seventeen Röchling-Rodenhauser furnaces, with a total capacity of about 57 tons; and one Frick furnace, with a total capacity of 12 tons. At a low estimate these furnaces would be capable of producing some 100,000 tons of high-grade steels per annum.

"It was inevitable that some trouble should have been experienced in the development of these furnaces. The metallurgist who is to use it is confronted with a device which provides him with a receptacle in which to handle his metal, of an unaccustomed shape; he has available a means for heating his metal more rapidly and to a higher temperature than is possible in the usual types of metallurgical furnace, and, finally, he finds that his molten charge is automatically and very effectively stirred, due to electromagnetic effects. Being of a conservative nature, he quails before such a wealth of improvements, and is inclined to upbraid the 'electrician designer' for wasting his time with such a 'box of tricks.' His interest has been aroused, however, and, with the aid of his valuable suggestions, improvements are rapidly being made in those points relating to both construction and procedure which may truly be said to come within his province.

"These remarks are made to emphasize the fact that success can only be obtained by means of the closest co-operation between metallurgist and electrician. An abundance of results have been recorded which prove beyond question that

the induction furnace is a device by means of which all the metallurgical operations requiring the melting and refining of raw materials for the production of finished steels can be performed with at least equal, if not better, results than can be obtained by any of the methods generally adopted."

Mr. Hården then discusses the outlook in various countries, with special reference to Sweden and Norway, Germany and particularly England. Concerning the United States the au-

thor may have held over his foreign rival, due to his having exclusive knowledge of those intricate processes for the production of high-grade steels, will long remain with him, and, so far as skill in manufacture is concerned, he must inevitably meet his rival on even terms. In other words, the magic of a Sheffield brand will have departed unless it is backed by a price comparable with that of a corresponding foreign brand. So far as export trade is concerned, the British manufacturer has this advantage over his foreign rival, particularly the American: that a large percentage of his raw material is in close proximity to the manufacturing center, while the manufacturing center is near the seaport. This advantage, backed by a reduction in cost of manufacture, such as may be obtained by the employment of induction furnaces, should ensure that the British steel maker will retain the large share of the world's markets for high-grade steels which he at present enjoys.

Two-Phase Combination Furnace

"The most interesting advancement so far unrecorded is the design of a two-phase induction furnace on the lines of the Röchling-Rodenhauser furnace, by means of which it is hoped to effect considerable economy by reducing radiation losses and by improving the electromagnetic conditions.

"The distinctive features of this new type of furnace will be seen from the diagram in Fig. 5.

"A and B represent the cores of two identical single-phase transformers, each designed to carry about half the load. C and D are the two primary coils, separated by annular spaces E and F from the lining shell G. The front and back of the furnace hearth, which is indicated by I, are connected by the narrow annular ducts J and K, which will contain the metal forming the two secondaries of the transformers. Provision is made to prevent the slag from entering and obstructing these ducts. The shaded exterior part represents the lining surrounding the hearth I and ducts J and K.

"It will readily be seen by a comparison with the diagrams 3 and 4 that this form of furnace has several advantages over the single and three-phase arrangements, both of which types have been built. The complication of the three-phase furnace hearth and roof were soon found in practice to be so great that the type has now been abandoned, in spite of the fact that the electromagnetic conditions, as compared with those in the single-phase furnace, were much improved. In the case of the single-phase furnace the shape of the hearth and roof is extremely simple, and many furnaces of this type are giving excellent results in practice. The electromagnetic conditions are, however, less satisfactory, and an improvement in this respect is desirable.

"In the arrangement of the two-phase furnace shown above, it is hoped to combine the good points of both the three-phase and single-phase types. It will be seen that the shape of the hearth is identical with that of the single-phase furnace, while, owing to the fact that the cores surround the narrow heating channels, and not, as in the case of the single-phase furnace, the wide hearth containing the greater part of the charge, which must, for mechanical reasons, be separated from the core by a considerable space filled with lining material, the magnetic leakage is considerably reduced and a higher power factor results.

"A further advantage is gained by the fact that the lining of the hearth may be designed with a view to reducing the radiation losses to a minimum, since the space devoted to this part of the lining will not have such an appreciable effect upon the electromagnetic conditions as is the case in the single-phase type. The use of the two-phase type does away with the necessity for introducing an expensive motor-generator set, with single-phase low periodicity generator, between the furnace and any existing two or three-phase supply.

"In the case of the larger size of furnaces, and if the periodicity of the supply is normally high, the power factor may be regulated by the installation of a rotary condenser. For a three-phase supply the regulating transformer, for varying the voltage at the furnace terminals and consequently the temper-

FIGS. 1 TO 4—PRINCIPAL TYPES OF SIMPLE INDUCTION AND COMBINATION FURNACES

thor says: "So far as future development in the use of electric furnaces is concerned, the prospects are far brighter in the United States and Canada, more particularly in the States, than in any part of Europe. Here exists an enormous and ever-increasing demand for home consumption, which under the present tariff laws must be met largely by home production. This production on a large scale and at consequently lower rates, coupled with the low cost of Atlantic freights, will probably make it possible, as in other industries, to compete with the makers in Europe, in spite of the long and costly rail freights between the center of manufacture and the seaport.

Production on an enormous scale will be as much the maxim of the American manufacturer of high-grade steel as it is with the manufacturer of other commodities. Here, then is an almost ideal field for the induction furnace, since the demand for high-grade steels must be great and the facilities for producing cheap electric power, either from water-power, gas or oil are at least as favorable as in any other parts of the world. . . . Although the number of electric steel furnaces at present working in America is far behind the number in Europe, it requires no abnormal prophetic powers to foresee that in a very few years America will create a record in this as in so many other industries."

As to the outlook in Great Britain the author says:

"In these days of easy and rapid communication, it is idle to suppose that any advantage which the British steel maker

ature, may be designed on the Scott principle. By designing the furnace transformers for normal-periodicity current the iron section of the core becomes much less than is the case with the low periodicities, which are essential to large single-phase furnaces.

"As a matter of interest to the electrician, I give a diagram, Fig. 6, of the switching gear and connections which would be employed for a two-phase furnace supplied with power from two-phase mains. The voltage-regulating transformer would be arranged for hand operation, and is preferably in mechanical or electrical connection with the circuit-breaker, in order satisfactorily to break the large inductive load before switching over from one step to another on the regulating transformer.

"The furnace itself, being in reality merely a short-circuited transformer, will stand the sudden switching on or off of high currents without any ill effects."

In Fig. 6 *A* is a voltmeter; *B*, ammeter; *C*, wattmeter; *D*, synchroniser; *E*, power factor indicator; *F*, voltmeter; *G*, voltmeter; *H*, to synchronous motor; *I*, to induction motor for starting synchronous motor; *K*, furnace transformer coils; *L*, regulating transformer.

The electrical load of an induction furnace is not subject to large fluctuations. "It is, indeed, almost entirely under the control of the operator, the slight automatic change in the electrical conditions being due to the effect of the chemical and thermal changes in the bath, and, since these only take place slowly, no ill effect results from it. This is particularly the case with a furnace used for the treatment of hot metal, since less thermal change takes place in the charge during the time of its treatment."

Construction of Lining

In discussing the heat insulation of electric furnaces, the author refers to Dr. Carl Hering's articles in this journal on the subject. As to the unit "thermal ohm," he says: "This nomenclature, I fear, is somewhat apt to be misleading, and will, no doubt, be improved upon." But "those of us who are interested in the question of electrical furnaces cannot but feel indebted to Dr. Hering for raising this most important question in so able a manner.

"In addition to its heat-insulating value, a lining must, besides being of sufficient mechanical strength to carry the charge, be capable of withstanding the internal strains set up by expansion, while at the same time it must be dense enough to prevent excessive percolation of molten metal through the interstices between the particles of which it is composed. Its chemical effect upon the composition of the charges is, of course, also of great importance.

"In any furnace all these qualities are very desirable, but in

FIG. 5—TWO-PHASE COMBINATION FURNACE

none so much as in the induction furnace, and in none are they more difficult to attain. The high temperature possible, the automatic motion of the molten metal, both most desirable characteristics when under control, and the peculiar shape of bath, make the design and construction of the lining one of prime importance.

"In the first 1½-ton induction furnace built by Dr. Kjellin, at Gysinge, an acid lining consisting of silica brick was used. It was found, however, that too much silica was absorbed by the steel, probably due to the eroding action of the circulating metal, and it was soon abandoned in favor of a basic lining, which was constructed as follows: 10 kg of finely ground

burnt magnesite were mixed with every 500 kg. of sintered magnesite, to which were added 40 kg. of Holland clay, reduced to a paste with water and some boric acid; when it was ready for ramming in the furnace round a suitable template. For a complete lining up to the level of the molten metal some 2700 kg. of this mixture was used. The lining above the level of the metal was finished with a course of magnesite brick. On this lining 28½ tons of steel from cold material, representing about 210 complete charges, could be produced.

"The use of water in bringing the lining mixture to a proper

FIG. 6—DIAGRAM OF CONNECTIONS

degree of plasticity, to enable it to be rammed into place, was improved upon later by the use of hot tar, with which it is possible to obtain a more homogeneous and less porous lining, better calculated to withstand the tendency of the molten metal to percolate through the pores.

"The Röchling-Rodenhauser furnaces at the Röchlingsche Eisen & Stahlwerke, at Völklingen, in Germany and at Vereinigte Hüttenwerke Burbach-Eich-Dölnelmeier Akt-Ges. at Luxembourg, are all lined in the following manner. The furnace castings are first protected by means of layers of firebrick, which also serves to a large extent as the principal protection against radiation losses and rarely require replacement. On the bottom surface of the firebrick is first rammed, by means of automatic stamps, to the level of the hearth bottom, a layer of a mixture of carefully roasted dolomite and tar, ground and intimately mixed in suitable mills. Templates of cast iron for shaping the hearth and the heating channel's are then placed in position, and more of the lining mixture is rammed round them, after which they are removed and the top of the lining finished off with dolomite bricks.

"The roof of the hearth and the heating-channel covers are formed of silica bricks carried in suitable frames. Before placing the roof in position the lining is dried by placing cast-iron rings in the channels, the temperature of which is raised gradually to a point just below the melting point of the cast-iron rings by increasing the current in the transformer winding. These rings may be well coated with graphite and oil to retard oxidation. As soon as vapors from the burning tar have ceased to be evolved, the roof and channel covers are placed in position, a charge of molten pig is run in and the temperature further increased to the maximum required to complete the final sintering of the lining.

"In a 4-ton furnace the time required to replace a worn-out lining may be analysed as follows:

Tearing out old lining and ramming in new 124 hours

Burning out tar with hot rings 6 "

Completing the sintering of the lining 6 "

"During the burning and sintering processes some 230 units would be consumed.

"Such a lining as described above will stand from 90 to 125 charges of hot metal, or from 360 to 500 tons, according to the class of steel produced, which determines the time required.

Lining Construction at Poldihütte

"I have already indicated some of the difficulties which have had to be faced in the design and construction of linings, and it will be of interest to give some description of a lining which has been evolved by the Poldihütte Co., a well-known Austrian firm, after much experimental work with a 4-ton tilting Kjellin furnace. This firm, who installed their furnace in January, 1908, early realized the importance of the lining question, and set themselves, with conspicuous success, to solve the difficulties involved.

"The problem was complicated by the fact that the furnace, in addition to being fitted with tilting gear, was mounted upon a carriage, and provision was made for rotating it round a vertical axis to facilitate teeming operations. Under these drastic conditions, with the usual type of rammed magnesite lining, it was found impossible to obtain more than forty-nine charges without a renewal of the lining becoming necessary, on account of the appearance of cracks.

"After much experiment, it became evident that no simple form of rammed lining was suitable for the conditions under which the furnace was handled, and tests were then made with a lining compounded of several layers of materials having different compositions, with a view to localizing the cracks which so rapidly appeared. Working on these lines, so much improvement was made that in 1909 the average number of charges obtained from a lining amounted to about 200.

"From this date improvement was rapid, as the following table of results showing the average number of charges obtained during a period of three months indicates:

First quarter of 1910.....	227	charges.
Second " 1910.....	250	"
Third " 1910.....	262	"
Fourth " 1910.....	288	"
First " 1911.....	386	"
Second " 1911.....	392	"
Third " 1911.....	401	"

"The final lining evolved, which is fully patented, is indicated in Fig. 7, representing a vertical section of the lining.

"The lining is constructed in the following manner: First the bottom of the furnace shell *M* is covered with a single layer of firebrick *A*; upon this a layer of magnesite brick *B* is laid, using as cement a mixture of magnesite powder, lime and water. The outside of the shell *M* is then laid with a single course of firebrick *C*. Round the inside of this firebrick, and round the outside of the cooling jacket *N*, are fitted spacing pieces of wrought iron, which are fitted into place in somewhat the same manner as the staves of a barrel, and form the templates for the asbestos-wool channels *D* and *E*. The spacing pieces have holes punched in the top ends to facilitate removal, and in the case of those round the cooling jacket *N* are held in place by a steel band, and in the case of those round the firebrick lining *C* by means of wood staging.

"Cylinders built up of three or four sheets of cartridge paper and tracing cloth, with the smooth surface outside, are then placed in position at *G*, and strengthened temporarily by means of well-oiled sheet-iron cylinders. This prepares a space into which a mixture of well-roasted dolomite and tar carefully prepared is rammed. The remainder of the magnesite bricks *H* are now laid upon a sloping layer of magnesite sand *I*, using the same cement as before, while gradually, as the number of courses are increased, the sheet-iron cylinders holding the paper-covered rammed dolomite *F* in place, and which for ease of working are built upon parts, are withdrawn.

"In preparing the mixture for the lining *J* of the heating channel *L* much care is taken. It is made up of an equal proportion of three materials: First, high-grade 'Veit' or 'Stryan' magnesite, ranging in size from $\frac{3}{8}$ in. to $1\frac{1}{2}$ in.; second, similar material varying in size from $\frac{1}{4}$ in. to $\frac{3}{8}$ in.; third, fine crushed magnesite bricks from old linings, with which is mixed 1 per cent of finely ground 'Thomas' slag. Care is taken to remove all impurities, particularly metallic constituents as far as possible.

"Equal parts of these constituents are intimately mixed

with hot tar until a homogeneous substance is produced, which when squeezed in the hand forms into firm balls. Too much tar will cause the mixture to flow when rammed; with too little it will not bind well. Having prepared this mixture, it is rammed in while still hot on top of the magnesite bricks *H* up to the level of the heating-channel bottom. The channel template of well-oiled cast iron is then placed in position and the ramming completed.

"After drawing the spacing pieces forming the channels *D* and *E* and filling the spaces with asbestos wool, which may be used repeatedly for many linings, the channel template is removed and the lining is ready to be dried in the usual way with cast-iron rings electrically heated.

"To the first charge which is worked about 12 lb. of aluminium are added, with sufficient scale or rusty iron to oxidize it. The alumina formed fluxes the rammed magnesite, forming a surface which resists the percolation of the iron.

"The advantages of this lining are that the troubles due to vibration and expansion in all directions have been to a very large extent overcome. As regards its thermal insulating value, unfortunately there are at the present time insufficient figures available to determine the extent to which improvement in this respect over the more simple types of lining has been effected.

"The conclusions to be drawn from this brief survey of the induction-furnace position may be summarized in very few words. As in all things, there is room for further improvement, and I have tried to indicate upon what lines development is proceeding.

"Up to the present time the scope for the economic use, particularly in England, has not been wide, owing to the fact that they are still somewhat ahead of their time. All evidence, however, points to the fact that the growth of the demand, for which they, as instruments, will provide the supply, is fast reaching those dimensions required to demonstrate that induction furnaces are a necessity to the steel industry.

"Their inherent characteristics are of such value that it is safe to say that they will not be relegated to the limbo of forgotten inventions without leaving an abiding mark upon the history of this age of steel."

FIG. 7—SECTION OF POL-DIHÜTTE LINING

Silicon Castings for the Chemical Industries

Pure silicon is a metal of remarkable acid-resisting properties. This has long been a matter of common knowledge, but no use was ever made of it in the technical arts because silicon metal was not available in commercial quantities and also because no method was known of making silicon castings.

As stated in an article on the works of the Carborundum Company in Niagara Falls, published in our issue of May, 1909 (vol. VII, page 192), the Carborundum Company has been the first to produce pure silicon commercially, the process for its manufacture having been developed by its works manager, Mr. F. J. Tone, U. S. Patents 745,122, 833,427, 842,273 and 860,276 (see our vol. II, p. 3; IV, 464; V, 141).

That article contained some notes on the electrical furnace used for the production of silicon, some typical analyses of commercial silicon and a discussion of the various applications of metallic silicon. Among the uses it was mentioned that silicon was produced in the form of small castings, such as rods for electric resistances, but the difficulty of casting perfect forms of metallic silicon was noticed.

Since then great advances have been made in the development of a successful method of casting silicon as the result of long investigation which was attended with the greatest difficulties. All these have now been entirely overcome and it is possible by some recently developed processes to make castings of all ordinary shapes and sizes. Cast silicon chemical ware is thus placed within the reach of all chemical industries.

Properties of Cast Silicon

Density—2.5 to 2.6.

Electrical resistivity—0.15 ohms per centimeter cube at 18 deg. C., decreasing rapidly with rise in temperature.

Thermal conductivity—good (no absolute value determined).

Specific heat—0.176 (17 deg.-100 deg. C.).

Melting point—1430 deg. C.

Boiling point—2800 deg. (calculated).

Hardness—6 on Mohs scale.

Compressibility— 0.16×10^{-6} (least compressible of any element).

Coefficient of expansion— 5.39×10^{-6} at 100-200 deg. (less than glass or platinum).

Tensile strength—approximately 1000 lbs. per sq. in. (exceeds that of stoneware).

Resistivity of Silicon to Various Chemical Reagents

Sulphuric Acid: Sulphuric acid in any concentration under gentle evaporation has no action on silicon.

When vigorously boiling the loss in grams per square foot in 24 hours is as follows:

Concentration	Grams loss
10 per cent	.0592
20 "	.0829
30 "	.0799
40 "	.0681
50 "	.3197
60 "	.2634
70 "	.1657
80 "	.1391
90 "	.1273
95 "	after initial solubility of .0033 gm. action ceases

Fuming sulphuric acid readily attacks silicon.

Nitric Acid: Nitric acid either dilute or concentrated has little action on silicon. The loss in grams per square foot in 24 hours is as follows:

Concentration	Vigorous Boiling	Gentle Evaporation
5	.0000	.0089
10	.0237	.0207
20	.1391	.0355
30	.2102	.0296
40	.1539	.0888
50	.2072	.1509

Hydrochloric Acid: This has a slight but continuous solvent action on silicon.

Hydrofluoric Acid: This acid attacks silicon vigorously.

Chlorine and Chlorine Liquors: Silicon metal appears to be highly resistant to these reagents in practice.

Phosphoric Acid: This shows a continuous but slight attack which does not altogether disappear. This results in a slight turbidity in the product treated.

Alkalies: All alkalies readily attack silicon.

Uses of Cast Silicon

Silicon is used in the form of pipes for the conveyance of acid gases at a high temperature from stills to condensers, also in the construction of the condensing batteries themselves, proving much more efficient than stoneware owing to its high thermal conductivity and ability to withstand sudden changes in temperature. Silicon pipes are also used for the transportation of hot liquid sulphuric and nitric acids. It cannot be used for hydrochloric acid unless the discoloration resulting from the slight solubility is immaterial.

As a lining it is used in centrifugal pumps, acid valves and pipes for the elevation of corrosive liquids by compressed air, and for the construction of plows in ore roasters it has proven efficient.

Cast silicon is also being used in the form of shallow pans and pots for the concentration of zinc chloride solutions, sup-

planting the enameled stoneware vessels which are rapidly destroyed.

Cast silicon ware is produced in practically all shapes required by the chemical industry, such as pipes, evaporating vessels, receivers, tile, alembics crucibles and pump parts. Castings are preferably made at least $\frac{1}{2}$ inch in thickness, excepting pipes less than 2 inches in diameter, which can be made with a $\frac{3}{4}$ -inch or $\frac{1}{4}$ -inch wall. In the designs of silicon apparatus sharp corners and sharp bends must be avoided so far as possible.

In comparing the cost per pound of silicon castings with the cost of special iron castings used for acid work, attention is called to the low specific gravity of silicon. In silicon castings there is required only one-third the weight of an iron casting of the same form.

Notes on Chemistry and Metallurgy in Great Britain

Institution of Electrical Engineers

The Research Work Committee's report, which the council adopted at a meeting on the 12th of December, advises that the scope of the research work undertaken by the Institution should be such as would avoid over-lapping the work of other societies, and should be confined as far as possible to (a) the organization and correlation of research work in electrical engineering, and (b) the organization and supervision of specific researches in subjects connected with the electrical industry, and the allocation of grants in aid of the same.

The former should include (1) the establishment of a general committee for research to which investigators would be invited to send particulars as to the subject and character of the researches they are undertaking. Members of the institution would also be invited to communicate to this committee any special difficulties they had encountered which called for investigation and to make suggestions for subjects for research; (2) the collection and publication of particulars of plant available for special testing and investigation work in the various laboratories, together with a list of the subjects in which researches have been carried out; (3) the compilation and publication of bibliographies of specific fields of research.

With regard to the heading (b) the committee consider that it is desirable that the institution should originate and direct researches on certain subjects, and suggests that the General Research Committee should have power to appoint sub-committees of experts to deal with researches in selected subjects. Firstly, a series of investigations might be initiated on "the electrical properties of materials," which would deal with such matters as magnet-steel, copper, carbon, paper, rubber, mica, porcelain, oils and varnishes, etc., for which fuller data are required.

The method of co-ordination in research is essentially German in its origin, and has been productive of immense benefit to German science. It may confidently be anticipated that if the recommendations of the Committee of the Institution are loyally carried out very valuable results will be attained.

The Electrolysis of Nitric Acid Solutions of Copper

At the November meeting of the Faraday Society J. H. Stansbie read a paper dealing with this subject. Under ordinary conditions the deposition of the whole of the copper from nitric solutions is practically impossible. In the electrolysis of such solutions nitrous acid is formed, and the fact that this acid has a material action in the solution of copper by ordinary nitric acid suggested an explanation and a partial remedy. Investigation demonstrated that the amount of copper remaining in solution was greatest when the quantity of nitrous acid formed was greatest.

The remedy proposed by the author consists in the addition of sulphuric acid, and the employment of a rotating cathode. He suggested that the effect of adding sulphuric acid is partly that it affords preferential conductance and so reduces the production of nitrous acid; and also that it forms with nitrous acid a nitro-compound having much less solvent action on cop-

per than nitrous acid has. The rotating cathode almost entirely prevents the redissolving of the deposited copper; and thus, with due care, only a slight trace of copper remains undeposited.

Electrically Refined Nickel

Experiments with an electric furnace for refining nickel, at the Technical College, Trondheim, which have extended over a considerable period, have given very good results; and it is claimed that an electric furnace for the commercial production of metallic nickel has been successfully devised. The Kristiansand Nickel Refining Works will shortly be enlarged to turn out twice their present output; and it is probable that the new furnace will be tried there. The production of nickel in this furnace is stated to be quite satisfactory in metallurgical respects.

The Institute of Metals

Hitherto the annual general meeting of the Institute of Metals has been held in January; but the forthcoming meeting will be held instead on the 11th and 12th of March at the Institution of Mechanical Engineers. Dr. G. D. Bengough will present his second report to the Corrosion Committee which will embody the results of the condenser corrosion tests which have been in progress during the past nine months or so. A committee has been appointed to deal with the nomenclature of alloys; and another committee has been instituted to assist the Dominion's Royal Commission in inquiries as to the supply of non-ferrous metals and their ores.

The nomenclature committee will consist of nine members of the Institute of Metals and one member each of the Institution of Electrical Engineers, the Institution of Mechanical Engineers, the Institution of Naval Architects, the Institution of Engineers and Shipbuilders in Scotland, the Northeast Coast Institution of Engineers and Shipbuilders, and the Society of Chemical Industry.

The Physical Society

The annual exhibition of scientific apparatus, which was held at the Imperial College of Science on the 17th of December, was well attended, and the exhibits fully maintained the standard of former displays. Messrs. Evershed and Vignolles showed a new type of testing set reading up to 5000 megohms; and Messrs. Elliott Brothers' instruments also deserve mention. Messrs. A. Gallenkamp & Company exhibited a laboratory electric furnace in which windings of high resistance wire having a melting point of 1537 deg. C. are substituted for platinum.

Messrs. Gambrell Brothers had on view their new Jordan convection-radiometer and thermo-galvanometer for measuring small and fairly constant thermal changes. The Cambridge Scientific Instrument Company's exhibit included a double range indicator designed for taking steel-hardening temperatures with a thermocouple, and the Whipple temperature indicator. The Foster Instrument Company had their graphic recorder for giving records of temperature with a fixed-focus radiation pyrometer, a thermocouple, or a resistance thermometer, or, alternatively, for recording current or voltage. Mr. R. W. Paul showed several fine single-pivot instruments, an Irwin astatic dynamometer which is not influenced by external fields, and high frequency capacity and inductance measuring apparatus.

Messrs. H. Tinsley & Company exhibited a new type of Drysdale phase-shifting transformer, giving constant voltage at all angles and correct to 12 minutes of phase-angle. The Weston Company had a good assortment of instruments; and the degree of accuracy claimed for some of the direct-current examples is such that they could, for many purposes, be substituted for potentiometers. Messrs. J. I. Griffin and Son gave prominence to gyrostatic apparatus, including the Gray-Burnside motor gyrostat for demonstrating practical applications of the gyroscope and a gyrostatic compound pendulum which has a motor-gyrostat for its bob.

Messrs. Alex. Wright & Company showed improved apparatus for the determination of the amount of fire-damp in

air and for the accurate estimation of fire-damp, carbon dioxide and oxygen in the atmosphere in mines. The Marconi company exhibited the radiogoniometer, a new instrument for locating the direction of an emitting source or for regulating the direction of propagation; the British Wireless Telegraph Company showed a vibration proof crystal detector; the Dubilier Electrical Syndicate's main feature was high-frequency apparatus; and Messrs. Nalder Brothers and Thompson had a good exhibit of electrical instruments.

Excellent optical instruments were shown by Messrs. E. Leitz, Messrs. R. & J. Beck, Messrs. J. H. Daelmeyer, Messrs. Carl Zeiss, and the Westminster Engineering Company, but particulars of these and other meritorious exhibits would occupy much more space than is available. Mr. S. G. Brown gave a useful lecture on "Some Methods of Magnifying Feeble Signalling Currents."

The Greenwich Generating Station

Advice gratis is not always worthless, and had the London County Council condescended to give due consideration to the criticisms which appeared in certain technical journals and elsewhere on their decision to put down large low-speed reciprocating engines at the Greenwich tramways generating station, although the turbine had been proved to be unquestionably far superior in all respects for driving generators of large output, some hundreds of thousands of pounds would have been saved to the ratepayers. Three 3500-kw reciprocating sets have been running only about 6½ years, and during the greater part of this period—since the second part of the station, with its equipment of turbine plant, was completed—they have only been called on to supply a very moderate proportion of the output.

Now two of them will soon cease from their stately and ponderous 94 r.p.m. to be replaced by two 8000 kw turbine sets, in the same space; for the Highways Committee has arrived at the conclusion that the turbines will give the 9000 extra kilowatts with a net annual reduction of the coal bill to the extent of some £14,000 or more; and it is proposed to discard the remaining reciprocating engines and replace them with turbo sets of 8000 kw each in the not far distant future.

The aggregate generating capacity of the station will then be 52,000 kw against 34,000 kw at present; while the saving in coal will be something like £25,000 per year at a moderate estimate. Of course, the L. C. C. will want to make the best of a bad bargain and dispose of their magnificent engines with double H.P. and L.P. Corliss cylinders for a good round sum; but the report of the Highways Committee is such a splendid testimonial to their coal-consuming capabilities, as compared with turbines, that the prospect of their fetching more than a tithe of their cost may be much more remote than that of consignment to the scrap heap.

Clyde Shipbuilding

During the eleven months ended on the 30th of November, 258 vessels, having a total of 588,806 tons were launched from Clyde yards. The tonnage for November alone was 71,658 for twenty-nine vessels, and takes second place in the monthly tonnages of 1912. Exact figures for December are not yet obtainable; but a thoroughly reliable estimate puts the Clyde total for the year at 650,000 tons, or 20,000 tons more than in 1911, which was the highest hitherto. This means that more than 50 per cent of the tonnage for the whole of England this year has been put afloat on the Clyde. The warships built on the Clyde this year include the Ajax, 23,000 tons, super-dreadnought, three cruisers, two depot ships, one survey ship, and six destroyers. The liners numbered sixteen, of which four were for the P. & O. Company and five for the British India line.

Engineering Imports and Exports

The returns issued by the Board of Trade for the eleven months ended the 30th of November, show material increase in all descriptions of engineering imports and exports, except imports of ships, as compared with the corresponding period

of last year. Imports of iron and steel, including manufactures, amounted to £11,713,216, and the exports to £44,279,332, the respective increases being £1,578,416 and £4,248,897. The imports of other metals, including manufactures, reached £28,358,042, an increase of £3,294,028; and exports were £11,223,953, an increase of £1,117,744. Electrical goods were imported to the value of £1,320,182, an increase of £23,334; and were exported to the value of £4,049,758, an increase of £1,442,706. Imports of machinery totalled £6,206,125, an increase of £890,569; and exports went up to £30,418,438, an increase of £2,091,938. Imports of new ships are valued at £32,172, a decrease of £30,321; but exports touched £6,237,295, an improvement of £1,340,263. Taking the month of November alone, imports of iron and steel increased £197,664 and exports were £529,125 better; in other metals imports and exports rose £711,533 and £173,450 respectively; imports of machinery were £87,275 higher, and exports increased £34,060; imports of ships increased £4,020, while exports went up £88,303; but electrical goods showed decreases of £8,973 in the imports and £15,775 in the exports.

Market Prices—December

Tin has been on the whole, quiet, considering the usual character of its fluctuations. Opening at £226 it was up to £227 3/4 on the 2d, and dropped away to 225 on the 4th, and £224 on the 9th. On the 10th it was again rising and reached £227 1/2 on the 18th, and closes at £228-10.

Copper has had a downward tendency, opening at £76 1/2 and dropping to £74-5 by the 6th and £73-5 by the 17th. It then recovered in tone and was £75 1/2 on the 20th and finally closed at 76.

Cleveland has been fairly steady with downward tendency. Opening at 67/4 it had fallen to 66/8 by the 7th, but finished at 67/9.

Scotch Pig has been in sympathy with Cleveland, opening at 73/10 and dropping off after the 11th, it ultimately recovered to 73/9.

Haematite has been steady, opening at 82/-, rising temporarily on the 10th, but dropping again, it closes at 82/3.

Lead. Very steady along £18-10-0 with tendency to rise the latter part of the month; closes, however, at £18-10-0.

Synopsis of Recent Chemical and Metallurgical Literature

Gold and Silver

Grinding-Pans vs. Tube Mills at the Homestake.—The experiments in the regrinding of sand at the Homestake mine, South Dakota, have resulted in the adoption of tube mills in preference to grinding pans. The details of the practice with both machines are given by Messrs. A. J. CLARK and W. J. S. ARWOOD, in *Bulletin* No. 98, Inst. Min. & Met.

The regrinding machinery consists of seven pans each 5 ft. in diameter, and a tube mill 5 ft. by 14 ft.

The pans are a modification of the Wheeler type, arranged to maintain a continuous discharge at the periphery, the depth of discharge being adjusted by the use of overflow rings of varying height, which are readily mounted upon the permanent lower portion of the shell. This shell extends 20 in. above the base-plate and determines the minimum depth of discharge.

The pulp fed to the pans is introduced in a distributing hopper, cast about the central shaft and forming part of the miller carriage. This hopper is tapped with pieces of pipe through which the pulp is led to the bottom of the pan and discharged directly in the path of the millers.

The total weight of moving parts when the pan has been equipped with new millers, is nearly 2200 lb., to which total the millers contribute 860 lb. The pans operate at 38 r.p.m. grind a trifle less than 20 tons per day, and consume \$4.70 each.

Mercury is fed in small quantities to the pans and the pulp, after overflowing the pans, passes over amalgamating plates, one plate, 4 ft. 6 in. wide and 6 ft. long, being provided for each pan.

These plates are dressed twice daily, and the amalgam is removed on alternate days; the pan is cleaned up when new plates and millers are to be installed, usually about once in three weeks.

The tube mill, driven by gearing from an electric motor, and provided with a scoop feeder, is lined with siliceous blocks, formerly 3 in. and now 5 in. thick. Flint pebbles are used for grinders, experiments with ore having proved unsatisfactory.

The pulp fed to the tube mill is diluted with sufficient water to carry it freely through the pipes into which the concentrating cones discharge, and is delivered into a dewatering cone 3 ft. 6 in. by 70 deg. slope, which is mounted above the feed hopper of the tube mill. The thickened pulp discharged from this cone carries fully 62 per cent solids, but it is interesting to note that the cone remains clear of any accumulation of sand and a rod introduced at the top meeting with no resistance until it encounters the bottom of the cone immediately above the bushing.

As this adjustment depends entirely upon the discharge area, it is necessary to frequently renew the bushing, and at this point the life of a bushing is not more than two weeks.

The overflow of the dewatering cone is nearly free from solids, containing but a small quantity of sand, over 99 per cent of which will pass a 200-mesh screen. This is led around the tube mill and unites with the ground sand at the discharge where it dilutes the pulp sufficiently to carry it over an amalgam table, 12 ft. by 18 ft. of silvered copper.

The mill grinds 73 tons per day, and consumes 37.5 hp when driven at 27 r.p.m.

All pulp discharged from the grinding machines unites with the main stream of pulp before arriving at the second battery of classifying cones.

The pans show a slightly greater recovery of amalgam, but the excessive wear of iron more than offsets all other considerations, and on this account we are preparing to install tube mills for all future work in this department.

The loss of mercury at this plant amounts to 0.061 oz. per ton ground; the amalgam retorts about 20 per cent and has a gold fineness of 630.

The two types of grinding machine have been operated on similar material with a view to determining which is the better

suited for the work, and the conclusion arrived at is in favor of the tube mill. A comparison of the work done shows the pan to be more economical of power, but we consider, and experiments have shown, that if 30 per cent to 40 per cent more sand were fed to the tube mill, and the discharge elevated and returned to classification system, the tube mill would be at least equal to the pan in this respect.

The daily performance of the tube mill and pans is determined by timing the filling of a 5-gal. bucket ($\frac{3}{4}$ cu. ft.) and weighing the catch. Wherever possible the tippie is used for diverting the flow to the sampler. Suitables have been drawn up so that the tons per day and the water ratio can be read at a glance from these data. The readings are made twice a shift and averaged.

Assay samples of the feed to the pans and tube mill are taken with slotted-top hand samplers, and are used for assay and sizing tests. Similar samples of the ground product are taken from the tippie discharge, which prevents contamination from amalgam plates. Three samples of 1.5 A. T. each are taken for assay.

Tin

Cornish Tin Dressing and the Vanning Assay.—New light is thrown on Cornish tin dressing practice and the use of the vanning shovel, in a paper by W. FISCHER WILKINSON published in *Bulletin* No. 99, Inst. Min. & Met. The author presents data obtained during two years' residence in Cornwall as principal of the School of Mines, during which time he was enabled to see what was being done in the mills of the district, as well as to investigate certain problems in the mill which is run for the benefit of the students.

Cornish mines and mills are weak as to statistics. The units adopted, namely, "black tin," "pounds of concentrate per long ton," etc., are indefinite, unreliable and ambiguous. The use of the vanning assay further complicates the situation and clouds the actual conditions. It is only since the introduction of the chemical assay that the serious losses in concentration have been made apparent. It has been generally stated that mill recovery was in the neighborhood of 90 per cent, with additional saving in the stream works, but the author comes to the conclusion that the actual extraction of tin throughout Cornwall today is between 50 per cent and 60 per cent. This great reduction is due to the abandonment of the vanning shovel and the substitution of the chemical assay.

The author gives comparative tests between the vanning shovel and the chemical assay on five different lots of ore and concentrate of varying grades. The results by the former method indicate from 22 per cent to 95 per cent of the tin shown by the chemical assay, and the highest figure was obtained by vanning high-grade, coarse cassiterite. The shovel seems to be least reliable on low-grade material. The figures show that on Cornish tin ores averaging from 1 per cent to 2 per cent tin, the vanning shovel will be about $\frac{1}{3}$ below the real value, and that mill extractions calculated on this assay will be in error to that extent. Thus a mill that shows a recovery of 85 per cent by the vanning assay will in reality be making a recovery of about 56.6 per cent.

Examples are given of the work of two companies that give publicity to their technical results. The Cornish Tailings Company, retreating an old dump containing 17 lb. tin per long ton, saves 40 per cent in a modern plant. The Carn Brea & Tincroft Mining Company recovers 95.81 per cent by vanning assay, equivalent to 73.7 per cent by the chemical assay. This is considerably higher than the other mines appear to recover.

The author believes that the first step in improving the recovery is to keep accurate statistics of the value of the ore; to abandon the vanning assay as well as the practice of reporting the yield in "black tin." Proper attention to statistics would show where the greatest loss was being made, and would indicate the direction for improvement.

The practice at the King Edward mill of the School of Mines was to crush on stamps through 4-mesh battery screen, running the pulp over a Buss table where 42 per cent of the metal

was recovered in the form of a concentrate containing 32 per cent tin. The first-class middling from this table was screened, the oversize being reground and combined with the undersize for classification. The second-class middling was screened, the oversize being thrown away and the undersize sent to the classifier. The slime and fine sand also were classified. The practice of tabling removed a valuable concentrate and relieved the classifier of 15 per cent of the original weight of ore and 42 per cent of its valuable metal. The coarse product from the classifier was treated on a Frue vanner and the fine on a round table. The tailings of both these machines were retreated.

The author believes that the use of screens such as the Cal-low of Bunker Hill would permit the immediate rejection of much worthless material, as experiments showed that the undersize of such screening contained a high percentage of the metal. The mill returns compiled from the battery sample and the tin sold during the period 1910-12, gave a recovery of only 50 per cent. He shows from the test figures that there is much room for improvement.

Recent Metallurgical Patents

Iron and Steel

Unmagnetizable Steel.—A patent for an unmagnetizable manganese-titanium steel of FRIEDRICH KOHLHAAS covers about the same composition as his German Patent 231,499 of Nov. 13, 1909, viz., a steel containing from 9.8 to 10.3 per cent of manganese, 0.9 to 1 per cent carbon, 0.2 to 1.4 per cent titanium, 0.8 per cent silicon, and maximum 0.03 per cent sulphur and 0.015 per cent phosphorus. The German patent gives the silicon as 0.4 to 0.7 per cent. Steel of from 10 per cent on of manganese has a very low magnetic permeability: it can be magnetized only with extraordinary difficulty, being practically unmagnetizable. Such steel, however, is known to be too hard for being worked and its toughness is too low, the elastic limit being situated pretty near the breaking point. It has been found that this same steel can be successfully produced by adding to it an admixture of titanium in the above named proportions. The new product can be treated with comparative ease; its elastic limit is 47 per cent of its breaking strength, it is less magnetizable than pure nickel and cobalt, and it will lend itself more readily to the various uses of unmagnetic material. (13,440, reissued July 9, 1912; original 981,575 of Jan. 10, 1911.)

Gas Washer.—MR. MARK W. JOHNSON, JR., of Birmingham, Ala., has designed a new gas washer based on the idea of mixing the gas with a tangentially introduced spray of water and leading this whirling mixture of gas and vapor under and in close contact with a thin sheet of water streaming down the outer surface of a flaring nozzle. Water and gas then receive a strong centrifugal action in a circular ring chamber by means of which the outer stratum of water containing the concentrated impurities, such as dust, cinder, etc., can be diverted onto a hopper and from here to a separator. The cleaned gases bubble up through the center of the device and can be carried off. The separator has a suitable drain opening for blowing off mud and a port through which another part of the cleaned gas flows into the pipe line for use. The first named water spray is produced by a needle valve, which is described, together with the other details of the invention, in six special drawings. (1,034,403, Aug. 6, 1912.)

Various Furnace Constructions

Crucible Furnace.—The following arrangement of burner for heating a cylindrical crucible furnace with either gas or a liquid hydrocarbon, is claimed by DAVID REISINGER STEELE, of Curtis Bay, Md. Near the bottom of the cylinder is a housing projecting laterally from the cylinder to be used as a combustion chamber. It forms a passageway which communicates tangentially with the furnace chamber. A burner is arranged so as to direct the burning gases or the atomized liquid fuel crosswise or transversely into this passageway, the air entering through another pipe at right angles to the flame issuing

from the burner. The air thus delivered will mingle with the burning gases, divert them from their course and carry them into the furnace chamber. Owing to the tangential arrangement, they will be caused to whirl around the crucible on their way to the top of the furnace. In the case of liquid fuel a branch of the air pipe is connected to the burner in order to produce a spray of the combustible. The furnace can be mounted on trunnions and the pipes connected through a swivel joint to the stationary pipes. (1,020,090, June 11, 1912.)

Air-Cooled Open-Hearth Furnace.—Mr. HENRY KNUTH of Monterey, Mexico, designs a series of spaced air passages which extend transversely and in a straight line through the port arch of open-hearth furnaces. The ends of the passages are left open to have them visible from the furnace floor. The circulation of air through these passages is controlled independently, and in a number of claims it is described how these passages can be connected with each other and with inclined passages leading in various ways, as, for instance, from the front and rear walls upwardly to the side walls of the gas port. A metallic lining is inserted into the inclined portion of lower passages and the circulation of a cooling medium forced through. (1,044,788, Nov. 19, 1912.)

Eyesight Plate for Twyers.—The eyesight glasses in the peepholes of blast furnaces mostly become dirty and fouled and are exposed to the high heat of the furnace. Mr. JAMES B. ROGERS of Ashland, Ky., overcomes this trouble by fastening to the cap of a twyer a rotatably mounted plate provided with a number of holes of the same or larger sizes as the peephole in the cap. Glasses can be inserted into the holes of the plate. By rotating this plate or shutter, the peep sights or glasses, or the larger opening can be brought into or out of register with the opening in the cap or furnace member. If necessary, the same holes can be used for introducing through same a pyrometer or pipes for gas, steam, etc. The invention is equally suitable for all kinds of furnaces in which it is necessary or desirable to have a peephole. (1,041,189, of Nov. 26, 1912.)

Hydrocarbon Furnace.—Mr. JOHN C. SCRIVNER of Madison, Ill., claims the construction of an oil heating furnace into which the burner is introduced from one side near the bottom. While other furnaces mostly have a fire bridge built on the bottom of the furnace, the peculiarity of this invention consists in the roof and side walls of the furnace being slotted, the slots being disposed downwardly and forwardly toward the burner. A removable bridge wall extends through these slots from the top toward the burner, and ends in close proximity thereof, somewhat above the body portion of the furnace bottom. This bridge wall can be a metallic one. The arrangement of the blast wall under an angle is supposed to distribute the heat more evenly. (1,003,522, Sept. 10, 1911.)

Reversing Valve.—Mr. HARRY BURNLEY ROSE of Johnstown, Pa., claims the invention of a new style of something similar to the Forber valve. One of the advantages of his swinging, oscillating type of valve is that it possesses means whereby it may rest and be shifted from one position to another by mechanism which will be submerged in the water-seal when the valve is seated, and thus be protected, while the operating mechanism is entirely accessible and exposed to view on the outside of the hood. This facilitates ease and economy of maintenance and operation. Furthermore the valve can be easily withdrawn and another one substituted without delay, thereby obviating and shortening in time the strenuous labor under the influence of intense heat and noxious gases. (1,045,749, Nov. 26, 1912.)

Mr. E. A. Grönwall, of Ludvika, Sweden, who is well known also in this country, was married on January 27 to Miss Märta Rydberg of Stockholm. Mr. Grönwall, jointly with Messrs. A. R. Dindblad and O. Stallhane, started the experimental work on the smelting of iron ore in the electric furnace, which was later taken up by the Jernkontoret and led to a new electrometallurgical industry in Sweden and Norway.

Producer Gas as a Substitute for Oil for Furnace Work.

The constantly increasing price of fuel oil, coupled with the assurance of the oil companies that such oil will never again be an economical proposition for commercial fuel purposes has brought both producer gas and the use of coal dust prominently to the front as economical and efficient methods of manufacturing a substitute for oil for all operations where high and low heats are essential.

The use of coal dust is noted in a separate article. In this article some interesting figures are given on the use of producer gas for furnace work as made by the Loomis-Pettibone gas producer, built by the Power & Mining Machinery Company, of Milwaukee.

The Loomis-Pettibone system manufactures a clean, fixed gas from bituminous or anthracite coal and coke, and, in addition, wood and other refuse containing carbon may also be gasified.

In the Loomis-Pettibone system a water gas containing 250 to 275 B.t.u. per cubic foot is manufactured intermittently with the production of a lean producer gas, containing from 90 to 105 B.t.u. per cubic foot. The water-gas can be used for all purposes where high temperatures, without regeneration, are necessary, as in manufactories carrying on a large variety of brazing, small forge work, etc., where the furnaces are small, and distributed over a large area. Temperatures ranging from 2500 to 2900 deg. Fahr. are easily obtainable with this gas, and with properly constructed furnaces, it is possible to contain an added efficiency in operation so that the quantity of B.t.u.'s in the gas used will be only 66 to 80 per cent of the B.t.u.'s furnished in oil as used in approved oil furnaces for the same purposes.

Water-gas does not cause the metal forged to scale like oil, and with it it is possible to get much closer regulation of furnace temperatures.

By mixing a small portion of the water-gas produced with the lean producer gas, a mixed gas of from 125 to 135 B.t.u. is obtained, which gas may readily be used for operations such as annealing, tempering, case-hardening, babbiting, and all such purposes, where temperatures to be obtained do not exceed 1700 deg.

One long ton of good bituminous fuel when gasified by this system will generate 40,000 cu. ft. of water-gas and 120,000 cu. ft. of producer gas, as described above, and there are installations in daily operation which exceed these figures as to output.

If conditions are such that it is possible to install gas engines, part of the lean producer gas can be used to furnish power.

In cases where it is impossible to make use of the producer or mixed gases of the Loomis-Pettibone system, where the heats required are all at high temperatures the Power & Mining Machinery Company recommend their blue water-gas apparatus, operating on anthracite coal and coke. This apparatus makes a water-gas containing 330 B.t.u. per cubic foot from the fuels specified above, and, when equipped according to this system with high-pressure blower, steam drying and distributing apparatus, quick-operating valves, etc., will produce 50,000 to 60,000 cu. ft. of such gas per ton of fuel gasified when operated properly according to instructions. This gas possesses all of the qualities of the water-gas made in the Loomis-Pettibone apparatus, and, in addition, has a higher heating value per cubic foot.

In the present note it was merely intended to give figures of the results obtained in commercial practice in order to provide a basis for estimating the possibilities of gas in competition with crude oil. As to the description of the construction of the Loomis-Pettibone Gas Producer and Blue Water-Gas Plants reference may be had to Bulletin 100 of the Power & Mining Machinery Company, of Milwaukee, which is entitled "Loomis-Pettibone Gas Generating System, Gas for Furnace Work."

Pulverized Coal as a Fuel

By A. W. Raymond

The recent increased cost of crude oil has turned the attention of fuel oil users on pulverized coal as a substitute, instead of reverting to the old producer gas plant, and experiments which have been carried on along these lines have demonstrated not only its adaptability and efficiency, but also its economy. When properly pulverized coal will yield higher temperatures and more B.t.u. per ton than can be obtained from a like amount of coal used in a producer gas plant while the equipment is about one-third the cost.

The method of burning the coal dust is very simple. A pipe conducts a blast of air into the furnace and the coal dust is automatically introduced into the air at a point about one foot from the nozzle of the pipe. Any method of feeding the coal, such as a screw conveyor, which will insure a regular and uniform feed will be found satisfactory. The temperature in the furnace and the length of the flame is very easily controlled by the velocity of the air blast and the quantity of coal dust mixed with it. In order to get complete combustion of the coal to carbon dioxide the mixture of air and coal dust must contain at least four times the calculated amount of oxygen required.

For the benefit of those readers who are in doubt as to the adaptability of coal dust as a fuel, the writer would like to say that to his personal knowledge pulverized coal has been burned successfully for the last ten years in a number of large plants. Among these plants are the Canadian Copper Co., at Copper Cliff, Ont., Canada, where powdered coal is burned in the smelting furnaces, and the Chicago and Hamilton, Ont., plants of the International Harvester Co., who use it as the source of heat for their annealing ovens. These plants pulverize the coal to such a degree of fineness that 98.5% of it will pass through a 100-mesh sieve.

The writer has also recently had occasion to come in personal contact with some experiments on a regenerative open-hearth furnace. Two heats of open-hearth steel have been made with powdered coal as a fuel and very even and high temperatures were maintained with coal pulverized so that 91% would pass a 200-mesh test sieve. The checkers showed no sign of plugging and the steel was as free from sulphur as when producer gas or fuel oil is used. For these tests the coal was ground on a pulverizer depending on screens to get a fine product and it was clearly demonstrated that the cost of grinding the coal to the necessary degree of fineness on this type of machine was prohibitive, so the reader can deduce that all that is needed to make the use of pulverized coal a regenerative type of open-hearth furnace a success is a method of pulverization which will yield a product as fine, or, better still, even finer than 91% through a 200-mesh test sieve.

The knowledge which has been gained from investigation, experiences, and comparative tests shows the Raymond four-roller mill, fitted with what the Raymond people call their vacuum air separator, to be an excellent method of pulverization which will answer the purpose. Averaging these tests which cover a period of over a year's time on fourteen pulverizers, the cost per ton of pulverizing the coal so that 99.5% will pass a 100-mesh test sieve amounted to \$0.325. This figure includes the power used at a cost of 1.5 cents a kilowatt hour and shows a saving of \$0.211 per ton over any other method with which it was compared. Though the above tests only proved the necessity of a finely pulverized coal on a regenerative type of furnace, the writer holds to the belief and feels confident that the reader will agree with him that the highest efficiency in any or all cases can only be obtained when the coal is ground extremely fine and uniform. Let us now take up the process of properly preparing the coal for the burners step by step.

The coal must first be crushed so that it will all pass through a ring $1\frac{1}{4}$ " in diameter, as there is no machinery made which will reduce the ordinary mine run of coal to the required fine-

ness in one operation. Though not absolutely essential, it is generally conceded that the crushed coal should be dried thoroughly before pulverizing or burning, as dried coal can be pulverized with 15% less horsepower than the wet, and it is almost axiomatic to say that dried coal is more easily ignited and consequently gives higher temperatures and less ash. Actual experience has proven that drying the coal before pulverizing or burning it is a money saving practice. Excellent drying apparatus is manufactured by the Ruggles-Coles Engineering Co. After the coal is thoroughly dried it is ready to be fed into the pulverizer and the necessity of using the right kind of pulverizing machinery cannot be too strongly emphasized.

The pulverization of coal entails no danger from spontaneous combustion, providing the necessary precautions are taken. The pulverizer used must be one which does not heat up the coal; that is, one in which the friction is reduced to a minimum, and the danger of sparking against any iron in the coal is eliminated. A ball mill is impractical because the pusher plates behind the balls get very hot and will invariably cause the coal to take fire.

The first step is to select a pulverizer which delivers a cool product so that it can be safely stored for a day or two. Investigation will show the Raymond mill, before referred to in this article, to be such a pulverizer. This mill has another very important advantage in that the coal is never allowed to settle in the grinding chamber and for this reason the danger of an explosion in the pulverizer is entirely eliminated. These mills have been grinding coal in the United States and Canada for the last ten years and there is no record of any explosion or fires in, or resulting from, them. There is also another point to consider in the selection of a pulverizer.

The efficiency of combustion depends entirely upon the degree of pulverization. In other words, the finer the degree of pulverization the more economical the operation, the higher the temperature obtained and consequently a low percentage of a finely divided ash. In a regenerative type of furnace a low percentage of ash in a very finely divided state is absolutely essential, as anything else would clog up the checker work. Therefore, the coal must be pulverized very fine, the degree of fineness being determined by the cost of grinding as this cost must be kept as low as possible in order to make a powdered coal burning installation more economical than a producer gas plant. Here again we find the Raymond mill peculiarly adapted to coal grinding. The capacity is not limited, as in the case of a screen pulverizer, to the capacity of the screens, but every atom of power put into the mill is used in grinding the oversized coal, as the pulverized coal is removed immediately by the vacuum air separator. This principle is the very essence of economy as there is no waste of power.

Not only must the coal be very fine, but it must also be very uniform. Nothing but a very uniformly pulverized coal will maintain the steady and even temperatures which are required in almost every case. Particles of coal too large to pass an 80-mesh mean a resultant ash which contains a great many unused British thermal units, consequently, economical operation requires a very uniform degree of pulverization, which is impossible to obtain in a screen machine. A test made in the coal house of the Huron Portland Cement Co.'s plant at Alpena, Mich., and covering a period of six days showed that the coal ground on Raymond mills did not vary more than 0.2 in the percentage which passed a 100-mesh test sieve; in other words, the coal was ground so that never less than 98.4% or more than 98.6% would pass a 100-mesh test sieve.

The next question is, what is the cheapest method of pulverizing? In the writer's opinion the following figures obtained from the Omega Portland Cement Co. speak for themselves. These figures are averaged for a year's time and the coal was ground so that 98.5% would pass through a 100-mesh test sieve. In the one case the coal was ground in a Raymond mill and in the other it was pulverized in a hammer cage mill and finished on a tube mill. The cost of operation and repair, not including power, on the hammer cage and tube mill com-

bined was \$0.336 per ton, while on the Raymond mill only \$0.125 per ton, and the power required on the Raymond mill per ton of coal ground was a little less than half that required for the other method. Other tests comparing the Raymond mill with a ball mill used in the place of the hammer cage have substantiated the above figures.

The use of the Raymond mills in other large cement plants has resulted in a saving of two-thirds the labor and an increase of 12% in efficiency of combustion due to the high percentages of impalpable powder which is obtained by the Raymond system. One cement plant was able to make 13,500 tons of coal ground on Raymond mills, burning the same amount of clinker, as 15,120 tons ground by a different method would burn.

In brief, then, the installation for properly preparing the coal most economically should consist, in the writer's opinion, of gyratory crushers, Ruggles-Coles dryers and Raymond roller mills with vacuum air separators.

A New Electric Speed Indicator and Recorder

The Brown Instrument Company and the Keystone Electrical Instrument Company of Philadelphia, Pa., are placing on the market a new electric tachometer or speed indicator to accurately indicate, or record on a chart, the revolutions per minutes of a rotating shaft or wheel.

There are many operations where an accurate speed indicator is desired to be permanently connected to an engine or machine, and to show at a glance the speed at which it is running, or

FIG. 1.—ELECTRIC SPEED INDICATOR

to keep a constant record of this speed on a chart for the whole 24 hours.

The electric tachometer has the advantage of not only being exceedingly accurate, but that the indicating or recording instrument can be located at any desired distance from the shaft, the speed of which is to be measured. The instrument consists of a small generator, particularly designed for use with this tachometer. It generates 25 volts at 1000 revolutions per minute. On account of the voltage generated, an instrument, absolutely dead beat in operation, can be supplied. Instruments have been particularly designed by the above companies of unusually high resistance, exceeding 3000 ohms in each instrument, so that the length of leads connecting the magnet or generator and the indicating instrument have no effect on the

readings. For the same reason one, two or three instruments can be connected to the same generator without affecting the indications. This high resistance feature is exceedingly advantageous, for oftentimes after the generator and one indicating instrument have been installed, it is desirable to place a recording instrument in the office, or at another convenient point, and this can be connected to the generator without recalibration of the instrument.

In Fig. 1 is shown the standard Brown electric tachometer.

FIG. 2.—GENERATOR WITH TWO INDICATING AND ONE RECORDING INSTRUMENTS

generator, leads and indicating instrument as usually supplied while in Fig. 2 is shown a group of instruments connected to a generator driven by sprocket and chain, two indicating instruments and one recording instrument being connected to the same generator to both indicate and record the speed at three different points.

With many machines it is desirable to operate them at a certain speed to produce the best results, as for instance, in large machine tools it is desirable to know the cutting speed, and by use of this electric tachometer mounted beside the machine the exact speed can be noted at all times, and maintained as desired.

At all blast furnace plants where gas or steam blowing engines are in use it is necessary to run these engines at a constant speed so that a certain number of cubic feet of air per minute can be blown into the furnace. The revolutions per minute in cases such as this are of exceedingly great importance, and with the Brown electric tachometer with one indicator mounted near the blowing engines, on the engine itself, or on a switchboard nearby, and with a recording instrument if desired in the Master Mechanics' office, a perfect regulation and record of the speed can be secured.

There are many tests which constantly have to be made where an electric tachometer of this character will prove particularly advantageous. As an instance, we might cite the locomotive tests which are run by several universities and larger railroads which have testing departments in which the speed of the driving wheels can be readily determined.

Another use of this electric tachometer is on war vessels and merchant ships where it is particularly desirable not only to indicate the speed of the propeller shaft in the engine room, but also frequently at the same time in the chart house and on the bridge.

A bulletin on this new electric tachometer which has some radically improved features may be obtained from the manufacturers.

A New Temperature Recorder

At the New York Automobile Show which closed last week we had the pleasure of making the acquaintance of a temperature recorder of striking novelty. It is built by the Leeds & Northrup Company, of Philadelphia.

While it is new in so far as it has not been described before, yet it has been in use in various plants under quite different conditions in order to test it thoroughly in practical use. The development of the instrument covers more than five years. A large number of models was made and rigorously tested. In

FIG. 1.—TEMPERATURE RECORDER

addition to tests of complete instruments, every important part was subjected to prolonged tests for wear and other objectionable features. In addition to tests in their own laboratory the Leeds & Northrup Company had a number of instruments of each type in operation in the shops of large steel mills and in other works where they could be watched under such exacting conditions as are associated with temperature measurements. The National Bureau of Standards used one of these recorders on shipboard of the scout cruiser *Salem*. The instrument in question was sensitive to 0.05 deg. C. and proved perfectly satisfactory. If memory serves us right, the boat in question is considered one of the shakiest in the navy.

One striking novelty of the design is shown in the outside appearance of the apparatus in Fig. 1. It is the fact that the whole mechanism of the recorder is exposed to view and inspection. The whole apparatus consists of standard parts. These parts are in general of dimensions and strength comparable to the parts of a sewing machine. The design is such that each part may be removed and replaced easily. If necessary, a recorder could be entirely dismantled and reassembled with the aid of two screwdrivers and two standard wrenches. If a part is damaged a duplicate standard part can be inserted. These recorders have

FIG. 2—DETAILS OF MECHANISM

been developed to take down a single curve or several curves at the same time. In this article we deal with the single-curve recorder only.

These recorders can be used either with resistance thermometers or with thermocouples. If the recorders are used with a resistance thermometer the connections are those of a Wheat-

stone bridge. If the recorder is used with a thermocouple the connections are those of a potentiometer.

In these recorders the automatic balancing of the galvanometer of Wheatstone bridge is accomplished in the manner shown in Figs. 2 and 3. The motor drives the shaft (6) through a worm and gear at a speed of about 30 revolutions per minute. The shaft carries four cams (6B), (6C), (6D), (6D'), so located on the shaft that at the same time that (6B) raises the rocker arm (5), (6C) carries the clutch arm (2) away from the clutch disk (1).

The galvanometer, except at periodic intervals, swings freely about the location shown in Fig. 3. When the galvanometer is balanced the pointer lies at the position shown in Fig. 3, and as the rocker arm (5) is raised it lifts the pointer into the space between the two levers (4R) and (4L). If, however, the galvanometer is unbalanced, the resultant movement is shown in Fig. 2, the one lever or the other being lifted due to the interposition of the pointer between the lever and the rising rocker arm. The wings on the clutch arm can clear the cams 6DD' only when the clutch arm is horizontal, consequently, after being set as in Fig. 1, subsequent rotation of the shaft (6) returns the mechanism to the position shown in Fig. 3. When the

FIG. 3.—DETAILS OF MECHANISM

clutch arm is being tilted it is free from the disk; when it is returned it is in engagement with the disk and the two turn together.

Mounted on the disk shaft is the circular slide resistance. Also there is present on the shaft a wheel for communicating all motions of the shaft to the pen or print-wheel making the record. The movement of the disk, as described above, is always in such direction as will tend to restore a balance in the potentiometer or bridge circuit and the amount of movement is approximately proportional to the deflection of the galvanometer.

A pamphlet giving further details of the instrument may be had from the manufacturers.

International Commission on Annual Tables of Constants

The following gentlemen have agreed to serve on the American Advisory Committee of the International Commission on Annual Tables of Constants:

Dr. W. D. Bancroft, Dr. Carl Barns, Dr. A. L. Day, Dr. A. A. Michelson, Dr. W. A. Noyes, Dr. Ira Remsen, Dr. Jos. W. Richards, Dr. Theo. W. Richards, Dr. Alexander Smith, Dr. S. W. Stratton, and Dr. W. R. Whitney.

The first volume of the Annual Tables of Constants appeared last year and a review of it was published on page 572 of our volume X. The second volume will be out in the near

future.

Special Mixing and Grinding Machinery

The adjoining four illustrations show several mixing and grinding machines with various novel features.

Fig. 1 is a view of a special mixing machine designed for handling a pulpy mass. The machine illustrated had an extra special feature, as it was one of several designed and built for

FIG. 1—SPECIAL MIXING MACHINE FOR A PULPY MASS

handling a material which should not come in contact with iron, copper, steel, etc. These machines were constructed very heavy, water-tight in every respect, and all parts that could come in contact with the product were very heavily coated with tin.

The machines were equipped with special stuffing boxes, had bronze bushings in the bearings, and were equipped with quick-discharge valves of a special type. All surfaces were free from projections, so that they could be kept perfectly clean. These machines were approximately 30 in. in diameter by 7 in. long. They were sold with a guarantee of 1500 gal. capacity per hour, but actually produce 3000 gal. per hour each, with the use of 50 per cent less horsepower than guaranteed.

A Special Built Ball Grinding Mill

Figs. 2 and 3 show the first ball-grinding mill built with a seamless steel shell. This machine is really the regular type

FIG. 2—BALL GRINDING MILL

of pebble mill with the exception that instead of using pebbles for producing the grinding and mixing action, metal balls were used as the material to be handled is of a fluffy nature, and at the same time has an inclination to become sticky. For this

reason it was necessary to have the machine absolutely smooth inside, without obstruction, so that there would be no possibility of the material adhering to any point.

Fig. 3 shows the machine surrounded by a dust-proof discharge casing, which was made practically air-tight, so that either cold air could be circulated between the shell of the mill

FIG. 3—BALL GRINDING MILL WITH DUSTPROOF DISCHARGE CASING

and the casing or cold water could be run through the pipes surrounding the machine proper in order to keep it cool. The cylindrical part of the machine is 6 ft. diameter by 5 ft. long. The shipping weight was 18,000 lb. Its relative size can be seen by comparing it with the freight car standing behind it.

FIG. 4—PORCELAIN JAR MILLS

Fig. 4 shows the relative size of four different types of porcelain jar mills. It also illustrates part of a shipment of this class of machinery made to South Africa several months ago.

All these machines were personally designed by Mr. Paul O. Abbe, of New York City, to meet the special requirements for which they were intended.

The Basket Type Evaporator

For many purposes in chemical engineering the use of the basket type evaporator, developed and patented by the Swenson Evaporator Company, of Chicago, is found to be particularly suitable. The principal feature of this patented type is the inner shell located 12 in. outside the nest of tubes and providing additional heating surface which results in an increase of 8 or 10 per cent in the evaporative efficiency of the outfit.

The main advantage of this construction is not so much the increased heating area thus made available as the influence of this shell upon the direction and vigor of the circulation. Upon starting up an evaporator of this type, the evaporation from the space between the inner shell and the tubes starts almost instantly, resulting in a shooting up of a ring of liquor from this space long before evaporation begins in the tubes. With a

space for return current of about 8 in. between the inner shell and the outer shell of the evaporator, this type of apparatus has a splendid downward circulation rigidly directed into this space.

Sluggish circulation would be very troublesome in handling heavy or salty liquors, as it would result in incrustation of the pipes, resulting in slowing up the work by diminishing the value of the heating surface and not permitting the same concentration with a given temperature difference.

The matter of steam or vapor circulation around the tubes is very important. In the Swenson basket type about 8 per cent of the tubes are omitted in order to provide more generous circulating spaces. In this way the steam reaches all of the tubes as soon as it gets into the basket and both the operation and the wear are much more uniform. This is noticed by the equal evaporation over the entire boiling surface. As particular attention is paid to the removal of non-condensable gases the wearing qualities of the upper parts of the tubes are much increased.

An Interesting Agitator Test in Cyanide Practice.

To Dr. Wilbur A. Hendryx, who recently returned from South Africa, we are obliged for some interesting notes on an official test of the Hendryx agitator on the Rand.

One of the 18-ft. agitators, constructed by Head, Wrightson

then leaching the sands six to seven days, and treatment of slimes by decantation. A few of the more recent plants have installed agitation and filtration for their slimes. The average extraction as near as Dr. Hendryx was able to ascertain by the above methods, including amalgamation, is from 92 to 93 per cent.

In view of this situation, the results of the official test of the Hendryx agitator shown in the adjoining chart are interesting. They were so satisfactory that the Hendryx agitator was installed at the Wolluter Gold Mine, which has a capacity of 1,000 tons per day.

It will be noticed from the report that only one charge of slimes, 95½ per cent minus 120 was treated in two hours with 98 per cent extraction. The other four tests were made on the mixed product of sands and slimes, and it will be noticed by the solution assays that six hours was the longest period to get the extraction, and in charges 3, 4, and 5, that it was practically completed in 3 hours.

Taking these facts into consideration and the results on the slimes it appears quite reasonable to conclude that if these ores were ground to minus 90 mesh, 3 hours would be sufficient in which to treat this product. Most of the mills on the Rand to-day are grinding at least 98 per cent to minus 90.

It will also be seen that the percentage in cyanide loss is extremely small and this would substantiate the claim that

& Company, Ltd., of London, Eng., who are manufacturers and sales agents of the Hendryx apparatus in foreign countries, was sent down to Johannesburg, and turned over to the Mines Trial Committee of the Chamber of Mines of Johannesburg. This committee is composed of high-class mechanical and metallurgical engineers who represent all the groups of mines on the Rand.

The present general method of treatment on the Rand consists of stamping, amalgamating, tube milling, and classifying,

Dr. Hendryx has always made that the loss of chemicals was far less by the use of mechanical agitators than where air agitators were resorted to, as well as the time of extraction being much shorter, and that it also substantiates the fact that it is practical to treat sands and slimes together.

If the continuous process is adopted, the time for filling and discharging is eliminated, and this method of treatment is receiving serious consideration by the leading engineers on the Rand.

The First Combination Induction Furnace in Operation in the United States

By C. H. Von Baur

It was the desire of the Crucible Steel Casting Co. of Lansdowne, Pa., to be up-to-date in making steel for small and intricate castings, which prompted them to adopt an electric furnace.

The type selected is the Roechling-Rodenhauser induction furnace and the eighteenth to be placed in operation. Since then four additional R.-R. furnaces have been ordered by other steel mills. This one, the first to be placed in operation in this country, has a pouring capacity of 2 gross tons and

FIG. 1.—2-TON, 300-KW. ROECHLING-RODENHAUSER ELECTRIC INDUCTION FURNACE (FRONT VIEW)

operates at 300 kw from a 25-cycle, single-phase, 480-volt, 75 per cent power factor alternator, driven by a two-cylinder De La Vergne oil engine. This prime mover was decided upon, as it burns not only the heavy Mexican oils 16 to 19° Beaumé, but also the less expensive water gas tar. When running to capacity on single turn (12 hours), the furnace receives its electricity at not over 0.7 cent per kw-hour. The local lighting companies' price for current was more than twice as high as the above rate.

The furnace is 200 feet from the alternator. In order that the heat regulation might be accomplished within sight of and reasonably near the furnace, a remote control switchboard was erected about 30 ft. in front of and slightly higher than the spout. From this platform the furnace heat may be raised or lowered by pressing a button or shut off altogether by similar means. There is also here the controller which operates the motor for tilting the furnace. Electric instruments at both switchboards show at all times the degree of heat in the furnace. The blower motor supplying air for cooling the furnace transformer coils consumes 4.95 kw.

The bottom consists of magnesite and tar tamped in with pneumatic rammers. The roof is made of magnesite brick and lasts indefinitely.

The first steel was made in November 18, 1912. Since then a second lining has been put in. This was baked in more carefully than the first, taking about 24 hours at 50 kw. At the end of the fifth day's pour absolutely no sign of wear could be seen in the channels and only a slight scarification in the central hearth. The side walls usually last 3 weeks before thorough repairs are made.

At present it is the object to charge only cold metal, melt it and refine it. Room has been left for a preliminary melting furnace, to be installed when the capacity of the electric with cold charging on single turn has been reached. The furnace has a capacity of 1200 tons annually with cold charging,

and 2850 tons with hot charging, both on single turn.

One gratifying point about this type of furnace is that good steel can be made and was made with old open-hearth melters, right from the start, the reason being that the melter could keep his whole mind on making steel, without being distracted by an irregular heat supply, spot heating, frozen corners, or broken electrodes.

One important point in connection with the use of this electric furnace is the possibility of avoiding defective castings. In one run made there were no defective castings which had to be welded with the oxy-acetylene or the electric arc. Several castings have been sawed through and in every case they were found to be free from blowholes. Disregarding for the moment the fact that electric steel in the ladle costs less than crucible, small converter, or even steel made in the open hearth, either acid or basic, there is no doubt a large additional saving effected on account of the defective castings being reduced to a minimum.

Assuming that the molds are always in good condition, there are several causes which enable good castings to be made. *First*, the steel is thoroughly deoxidized and pours as well if not better than the best crucible steel. *Second*, while the steel has any desired temperature it is not "blowy," as converted steel is apt to be, nor do the castings suffer from "heat" or sulphur cracks. *Third*, a thoroughly reducing action is easily obtained toward the end of the heat without reducing the temperature as in the open-hearth.

The results obtained applied to a concrete case will show how great this saving is. A well-known foundry making miscellaneous small and medium size steel castings, bench work, etc., acknowledged the loss of 6% due to some of the above causes.

This foundry poured about 2400 tons annually, of which about 65% resulted in castings. The greater portion being small work, the average price was slightly over 10c. a pound. Electric steel in foundries has been known to reduce the "defects" to one per cent. The possibility of such a foundry adopting electric steel would result in sending 78 tons of castings more from the shipping room with the same output poured, and increase the profit \$17,500—a large additional interest on the investment.

An interesting feature when melting scrap in the electric induction furnace, is that the time required for a heat is reduced as the electric energy at the furnace terminal is increased; that is, the shortened melting time raises the attain-

FIG. 2.—VIEW OF FURNACE AFTER ERECTION

able efficiency of the furnace. There is another case of an induction furnace—a one-and-a-half-ton Kjellm—where a mixture of pig and scrap was melted with 060 kw hours per ton over a six-hour melting period, having 160 kw at the terminals, whereas 800 kw hours only were consumed during a four-hour period having 200 kw at the furnace. This gives a total efficiency of 50% for the six-hour melting time, and 60% for the four-hour melt.

In the accompanying figure the upper dotted line shows these conditions and proves the following formula:

$$\text{Tons melted} = \frac{\text{kw at furnace} \times \text{hrs.}}{\text{kw hours per ton.}}$$

The power should be kept at the furnace at a uniform rate.

This brings us to the case under discussion, where with a two-ton furnace a mixture of 1.38 tons consisting almost exclusively of scrap was melted and brought to a temperature as before indicated with 844 kw hours per ton in four hours and fifty minutes, or—

$$1.38 T = \frac{241 \text{ kw} \times 4.83 \text{ hrs.}}{844 \text{ kw hours per ton.}}$$

Drawing a parallel line to the foregoing case we reach the point the two-ton furnace has been designed for, namely, to produce 1.5 tons in 3.75 hrs. with 300 kw at the furnace terminals, or—

$$1.5 T = \frac{300 \times 3.75}{750}$$

Later on when a preliminary melting furnace of one form or another is installed, the output will be greatly increased, as 275 kw hours per ton will be sufficient to refine and degasify ordinary mixtures of pig iron and scrap. This would give a 10-ton output in 12 hours, greatly decrease the cost for electricity, and for the bottom, per ton of output, and decrease the overhead charges to 45% compared to cold charging.

The quality of electric steel made is the equal of crucible or

FIG. 3.—MELTING TIME AND EFFICIENCY

better. This high grade of deoxidized steel was made with about the following cost per ton:

Raw material (scrap).....	\$14.50	
Oxidation loss about 2%.....	.29	
		\$14.79
Current, 844 kw hours, at 7c.....	\$5.91	
Fluxes	.76	
Ore	.05	
Labor	1.50	
Tools, repairs and bottom.....	.76	
Cooling air for transformers.....	.12	
		9.10
Conversion cost		
Interest 5%, depreciation 10% per ton, about		1.50
Cost of one gross ton electric steel ready to pour	\$25.39	

When larger amounts of scrap are charged at a time, thus lessening the radiating losses due to the doors being open, and when 280 to 300 kw. is at the furnace instead of 250, the time for melting and deoxidizing will be shortened considerably, and the kw hours per ton reduced to about 750, which is near the European record for similar work in this size and type of furnace, exclusive of the heat required for baking in the bottom, and heating at night on single turn. It required 125 to 130 kw continuously to keep a full charge at temperature.

According to various calculations and tests, the amount of theoretical electrical energy necessary for melting down one gross ton of 2/3 scrap and 1/3 pig iron is given at 480 kw hours,

at a tapping temperature. This figure has also been given as 430 kw hours for mild steel when tapping at 1650° C.

The total electrical and thermal efficiency based on the observed radiating losses, with this furnace, is

$$100 - \left(\frac{130 \times 100}{300} \right) = 56.6\%$$

This figure checks up very well with conditions of this heat, which was hot enough, as already mentioned, to melt a 1 1/4-in. rod in 15 seconds, indicating a temperature well above 1650° C. If 430 kw hours per ton for melting is taken as the correct figure, no doubt 50 kw hours should be added to this for the additional superheating, which was estimated to be between 100 and 125° C. It takes about 40 kw hours to raise the temperature 100° C. Consequently

$$\frac{480}{844} = \text{approx. } 56\% +$$

The operation of this electric induction furnace, both economically and practically, is eminently satisfactory. For the past 12 years a Kjellin induction furnace has been in operation making tool steel, where its field in displacing the crucible is limited. For four years past it has been used in regular foundry operation, where a greater tonnage awaits it, but its largest field is in finishing open hearth and especially Bessemer steel for rails, as these have been found unbreakable in service.

The above furnace installation, including the generator, etc., was made by the American Electric Furnace Co., New York, the plate work and rolling portion by the Wellman, Seaver, Morgan Co., Cleveland, O., and the electrical parts by the General Electric Co., Schenectady, N. Y.

Obituary

Professor George A. Koenig, who was formerly a member of the University of Pennsylvania faculty, died on Tuesday, January 14, shortly before midnight, at the home of his son, Dr. Augustus Koenig, in Philadelphia. Professor Koenig was the oldest member of the faculty of the Michigan School of Mines, with which he had been connected as Professor of Chemistry since 1892; on January 7 he arrived in Philadelphia with his wife just a few hours before the death of his daughter, Miss Hilda Koenig.

Dr. Koenig is survived by his widow and two children, Dr. Augustus Koenig, a physician and metallurgist, and Mrs. George E. Nitzsche, an artist and portrait painter.

Dr. Koenig was assistant professor of chemistry and mineralogy at the University of Pennsylvania from 1872 to 1879, and professor of mineralogy and geology from 1879 to 1892, and professor of chemistry at the Michigan School of Mines since 1892. At the University of Pennsylvania he gave the first course in mining that was ever given in any educational institution in the United States. He took out a number of valuable patents. In 1897 he invented a new method of assaying without muffle, and later he invented an assay furnace to carry out these methods. In 1881 he patented a method for chlorination of low-grade silver and gold ores, and in 1911 a method of extracting vanadium from ores containing vanadium by which 95% of the vanadium could be recovered. He has prepared artificial crystals of arsenides, of which no natural crystals have ever been found. In 1885 he published his chromometric methods, a development of blow-pipe analysis, and in 1905 an elementary book of chemistry.

Dr. Koenig had a large and valuable collection of minerals which he presented to the Michigan School of Mines. Among the new minerals discovered and named by him are: Hydrotitanite, Randite, Leydyite, Alaskaite, Begerite, Rementite, Footeite, Paramelaconite, Mezapilite, Mohawkite, Keeweenawite, Stibiodomykite, Melanochalcite. He has also re-examined many other minerals and discovered diamond in meteoric iron.

Professor Koenig was born at Willstatt, Germany, on May 12, 1844. He was educated at the gymnasium at Kork, the School of Moravian Brothers, Lausanne, Switzerland, and at

the Polytechnic School, Karlsruhe, Germany, where he received his degree of Mechanical Engineer. From 1863 to 1865 he was a student at Heidelberg, and from 1865 to 1867 at the University of Berlin, where he received his degrees of Master of Arts and Doctor of Philosophy. Subsequently he attended the Mining Academy at Freiberg, Saxony, for a year.

He came to the United States in October, 1868, and manufactured sodium stannate from tin scraps in Philadelphia. He subsequently became the chief chemist of the Tacony Chemical Works of Philadelphia, and during the winter of 1870 he examined for the Lennig Company several old silver mines in Mexico, traveling much of the distance by stage coach, and enduring many hardships, and having several exciting encounters with the Apache Indians.

Dr. Koenig was held in high esteem, not only for his brilliant scholarship, but for his character and personal worth. He had those genial and magnetic qualities which won for him life-long friendships, not only among thousands of students who came under his charge during the forty years of his career as a professor, but also by his associates and co-workers in scientific fields. He was noted for his fairness and impartiality.

When he left Houghton, only a week before his death, the *Houghton Mining Gazette* printed the following editorial, in which is expressed the sentiment of those with whom he had lived for twenty years:

"The sympathy of the entire community goes out to Dr. and Mrs. Koenig in their bereavement. When the doctor left the other day to find relief and recuperation from his own physical ailments it was with sadness and sorrow that the local public learned that a leave of absence was necessary. And when this wholly unexpected blow, the death of his charming daughter, comes to add to his weight of sorrow the burden seems all the more difficult to carry.

"It is with no feeling of disrespect to the other members of the faculty of the Michigan College of Mines when we say that no man connected with that institution has such a place of love and friendship in the hearts and minds of the graduates and students and townspeople of Houghton as that held by Dr. Koenig.

"Standing high in his rating as a professional man, he stands still higher in the estimate of those qualities of personal charm that make a gentleman known and respected and admired by his fellows.

"We say these few words to let Dr. Koenig know that the sympathy and kindly regard of the whole people is with him in his present bereavement and to express the hope and belief that his wonderful mental strength will give him power to bear up and return to us in the spring renewed in vigor and physical health."

Personal

Mr. Kosaku Asano, metallurgist for the Ashio smelter, Japan, has been visiting American metallurgical works.

Mr. Gelasio Caetani, metallurgical engineer of San Francisco, will deliver a course of lectures at Harvard University in February, after which he expects to go to Europe for a short time.

Mr. A. R. Campbell has been appointed assistant manager of the Dearing, Kan., plant of the American Zinc, Lead & Smelting Company. He was formerly superintendent of the Needles Smelting & Refining Company, Needles, Cal.

Mr. Franz Cazin, metallurgical engineer of Denver, has been engaged in professional work in Mexico.

Mr. F. L. Clerc, of Boulder, Colo., is at Rockport, Texas, where he will stay until about March.

Mr. William Brown Dickson, recently elected president of the International Steam Pump Company, was born in Pittsburgh, Pa., on Nov. 6, 1865, son of John and Mary A. (McConnell) Dickson. He was educated in the public schools of Pittsburgh, Pa., commenced work at an early age and, in 1881,

secured employment at the Homestead steel works, which had just been built and placed in operation. After several years passed at manual labor in the mills, he was transferred to the office, acting at first in a clerical capacity, but subsequently received rapid promotion through various grades up to that of assistant to president and managing director of the Carnegie Steel Company. He became a junior partner in the Carnegie Steel Company, Ltd., in 1899. On the formation of the United States Steel Corporation in 1901 he accompanied Mr. C. M. Schwab to New York as assistant to the president of the United States Steel Corporation and later was elected a vice-president of that corporation, which position he held until May 1, 1911, when he resigned in order to retire from active business. Mr. Dickson was elected president of the International Steam Pump Company on Nov. 19, 1912. He succeeded the late Benjamin Guggenheim, who went down on the *Titanic*. Those who are familiar with Mr. Dickson's record in the steel industry do not hesitate to say that the International Steam Pump Company made a wise selection.

Mr. John V. N. Dorr, metallurgical engineer of Denver, spent the month of January in a trip to Central America, taking the West Indian cruise and visiting Panama.

Mr. John Howe Hall, formerly assistant superintendent of the Crucible Steel Department of the Bethlehem Steel Company, South Bethlehem, Pa., and for the last six years metallographer and metallurgist in charge of the research department of what is now the Taylor-Wharton Iron & Steel Company, having completed the installation of metallographic and testing equipment for the latter company, under the direction of Professor Henry F. Howe, vice-president and consulting engineer, and having perfected the operation of this department in investigating, improving, and controlling the quality of the output, has severed his active connection with them (retaining, however, a position as consulting engineer, and has opened an office at 165 Broadway, New York City, to engage in the general practice of consulting metallurgical engineering, making a specialty of steel-making processes, heat treatment and annealing, metallographic and testing equipment for the investigation, improvement and control of product, special steels, etc.

Mr. Charles W. Henderson, of Denver, recently completed an examination of the zinc resources and treatment methods of the Butte district in the interest of the United States Geological Survey.

Dr. Carl Hering, of Philadelphia, Pa., delivered a lecture on January 13 before the engineering students of the University of Virginia, on electrochemistry and electrometallurgy, in the course of which he sketched some of the latest advances in these branches and dwelt on the great possibilities of the future, mentioning many problems awaiting solution.

Mr. L. F. S. Holland, superintendent of the Smuggler-Union Company at Telluride, Colo., has returned to his work after an extended absence in Nova Scotia.

Mr. Milton M. Kohn, well known as the inventor of the replaceable-unit electric furnace, was one of the passengers on the steamship *Turrialba* of the United Fruit Company which was almost wrecked on Christmas Day. Mr. Kohn, who was returning from a trip to the Panama Canal, is none the worse for the experience.

Mr. C. B. Lakenan, general manager of the Nevada Consolidated Copper Company, was married recently to Mrs. Floribel White, of Los Angeles.

Prof. H. K. Richardson, of the electrochemical department of the Pennsylvania State College, has been chosen by the International Committee of the Y. M. C. A. to take charge of their scientific work in Chengtu, Province of Szechuan, China. The work is both scientific and religious. The scientific work is divided into two parts, one the training of science teachers for the new demand of the educated class of China, the other the taking care of a science museum where working models of inventions that have contributed to the progress of our civilization can be demonstrated.

Mr. Henry E. Wood, of Denver, visited New York City and other Eastern cities in January.

Digest of Electrochemical U. S. Patents

PRIOR TO 1903.

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

ORE TREATMENT (Continued).

653,538, July 10, 1900, Nathaniel Lewis Turner, of Salmon City, Idaho.

Relates to an apparatus for electrolytically depositing metals from solutions, such as gold-potassium cyanid, from the treatment of slimes, etc., and consists of a tank in which are suspended several concentric anodes, with means to detachably suspend separate cathodes between the anodes. Several rotating stirrers are provided which serve to keep the solution circulating. The anodes may be of iron or copper, and are covered with canvas; the cathodes are of lead or copper, and may also be covered with canvas. Provision is made for the examination and replacement of cathodes during the electrodeposition.

654,437, July 24, 1900, William Arthur Caldecott, of Johannesburg, South African Republic.

Relates to a method of precipitating gold from their cyanid solutions. Consists in passing the cyanid solution through precipitating boxes filled with mechanical mixtures of zinc shavings and lead shavings, as distinguished from zinc-lead couples, and shavings of zinc-lead alloys. The shavings are made by winding layers of zinc and lead, separated by paper, on a mandrel, forming a compact cylinder, and making the shavings as usual. The zinc and lead together form an electric couple, the paper forming a separator between them. It is stated that the mechanical mixture of shavings retains its efficiency longer than other forms of shavings.

656,305, August 21, 1900, Wilhelm Strzoda, of Falenze, Germany.

Relates to the solution of zinc compounds and ores in alkaline solutions, and the deposition of the zinc from the solution. Within a metal-lined tank are suspended anodes and cathodes, the metal lining also being connected as a cathode. Zinc ore or waste products are placed on the bottom, and an alkaline solution added to the tank. The solution may contain caustic soda, potash, ammonia, or any ammoniacal salt, either alone or with the addition of a salt of sodium, or of potassium, or the like. The continual evolution of hydrogen from the bottom of the tank keeps the ore, etc., stirred up in the solution. With sodium hydrate the soluble zinc compounds form sodium zincate, which is decomposed by the current depositing metallic zinc and reforming sodium hydrate. Other metals present, such as gold, silver, lead, tin, and cadmium, will be reduced to the metallic state, and if their compounds are also soluble, the metal will be deposited on the cathode with the zinc. The deposited metals may be separated in any usual manner. The solution can be separated from the residue by a filter-press and re-used.

657,032, August 28, 1900, Albion M. Rouse, of Denver, Colorado, assignor of one-half to William G. Shedd and Frank Brooks, of same place.

Relates to apparatus for dissolving the metallic values in ores, and for electroplating the dissolved metal. It consists of a tank in which ore is placed, and containing a central tube communicating with the outer space through perforations at the bottom. Within the tube, and just above the perforations is a rotary stirrer, or propeller which serves to pump the mixed solution and finely-divided ore pulp up through the central tube and down through the outer tank, causing continuous agitation and circulation of the pulp. By means of an anode and cathode located on opposite sides of the outer tank the dissolved metal is separated from the solution.

662,861, November 20, 1900, Emanuel Motz, of Jefferson, South Carolina.

Relates to an apparatus for electroamalgamating and electro-

dissolving and depositing metal from ores and solutions. It consists of a plurality of sections of a flume, connected so as to constitute a continuous channel for a flow of pulp and solution. On the bottom of each section, transversely to the flume, is a cathode plate of copper amalgamated, and parallel thereto and above it is an anode of lead suitably supported. Between two adjacent anodes is a vertically adjustable amalgamated metallic cathode plate the width of the flume, and which serves to agitate the pulp in the solution as the latter passes beneath the plate. The several sections are arranged in cascade so as to afford a continuous flow to the pulp. During the operation, any free gold is caught on the amalgamated cathode plates; the finely-divided gold will be dissolved by the solution with the aid of electrolysis and the dissolved gold redeposited on the amalgamated cathodes.

664,269, December 18, 1900, Carl Hoepfner, of Frankfort-on-the-Main, Germany.

Relates to a process of recovering zinc from ores and other materials. The zinc should be as carbonate or oxid, and is digested while under pressure and above normal temperature, with a concentrated solution of calcium chlorid and with carbon dioxide; or a mixture of this gas and air with zinc carbonate. The reactions are as follows:

The solution of zinc chlorid may then be enriched, if desired, and then electrolyzed. Any zinc chlorid remaining in the electrolyte is precipitated with hydrated lime. In the extraction of zinc from calamine (native carbonate) or roasted blende in contact with the carbon dioxide, or artificial zinc carbonate, solutions of calcium chlorid, solutions obtained in the ammonia-soda process, chlorate of potash, etc., may be used, or solutions of carnallite to which hydrated lime is added, may be used; the potassium chlorid in the carnallite may be used in the manufacture of chlorate of potash. The process is preferably carried out in a steam-jacketed digester containing a rotating stirrer.

664,537, Dec. 25, 1900, James Douglas, of New York, N. Y.

Relates to the extraction of copper from copper ore and matte by the chlorin or chlorin compounds resulting from the electrolysis of cuprous chlorid, and refers to his earlier patent No. 563,144. Broken pieces of ore or matte are placed in a suitable column, such as earthenware tubes, and the chlorin or gaseous chlorin compounds from the electrolysis of cuprous chlorid is passed through the ore or matte. The copper in the ore combines with the chlorin or chlorin compounds to form cupric and cuprous chlorids. If the acid electrolyte resulting from the electrolysis of the cuprous chlorid is used to leach the ore, the solution obtained is run back into the electrolytic vat.

668,842, Feb. 26, 1901, Albion M. Rouse, of Denver, Colorado, assignor of one-half to William G. Shedd and Frank Brooks, of same place.

Appears to be an improvement on his earlier patent No. 657,032, and relates to an apparatus for recovering gold and silver from ores. It consists of a plurality of tubs, having conical bottoms, with a valve and conduit connections to a vertical tube in which is a rotary stirrer to circulate the ore upwards through the tube and into the tubs through distributors. The ore is reduced to a fine pulp and mixed with about an equal weight of water, to which is added the solvent chemical, such as potassium cyanid, and supplied to the tubs, its temperature being maintained at from 90 deg. F. to 120 deg. F. by a steam pipe running through the tub. The pulp flows through a valve at the bottom of the tub, into a conduit leading to the upright tube, thence to the distributor consisting of a channel along the interior wall at the upper edge of the tub; the underpart of the channel being perforated, and provided with inclined chutes which give the pulp a swirling motion as it runs into the tub. This swirling motion of the ore causes the particles to rub against and clean each other, as well as thoroughly mix the ore and solvent. Anodes and cathodes are suspended in the circulating pulp, the dissolved metals being electrodeposited; the deposit of one operation serving as the cathode in a succeeding operation.

More Aspects of Conservation

We have often puzzled over the meaning of the stock apology of those publicists who advocate the restriction of water-power development on the ground that such powers "should be reserved for the people." Naturally enough, they do not as a rule trouble to explain exactly what the phrase means, if anything. Our thanks are therefore due to Secretary Stimson, who, at a hearing before the Foreign Affairs Committee in regard to the restriction of water-power development at Niagara Falls, made a dangerous descent to the definite. Advocating that the water should be developed to its fullest efficiency, he suggested at the same time that provision be made to give preference in the power permits to cities and to lighting and other public service corporations.

We could wish that it had been somebody with a lesser reputation for clear-headedness than Secretary Stimson who had made this suggestion. From an economic point of view, it verges on unsoundness, since it is doubtful whether in unrestricted competition for hydro-electric power the consumptive outlets favored by Mr. Stimson could, in the long run, hold out against outlets which, on account of their much superior load factor, form the natural market for such power. As is well known, the annual load factor (that is, the ratio of the average load to peak load during the year) of municipal lighting, and other similar public-service load, is usually in the neighborhood of 30 per cent. The much higher investment per h.p. capacity in an hydro-electric plant, as compared, for instance with a steam generating plant, results in a diminution in the difference of cost between hydro-electric power and steam-generated power as the load factor diminishes, and it is safe to say that in most localities the difference in cost on service of low load factor is not such as would be appreciable to the average consumer of such power.

What we wish particularly to call attention to, however, are the really remarkable aspects of Secretary Stimson's suggestion from the straight and sincere point of view of conservation. We are not going to touch, on this occasion, on the monumental waste of power at Niagara Falls enforced (for the present) by the treaty between the United States and Great Britain, but confine ourselves to the consideration of the 20,000 cubic feet per second permitted for American use by the treaty. This represents a definite amount of power. Even Secretary Stimson appears to appreciate this, and is sufficient of a conservationist to desire that it be developed "to its fullest efficiency," whatever that may be. It never seems, however, to have occurred to him that the principles of conservation demand, in the first place, that the power be utilized to its fullest efficiency.

Seventy per cent of all hydro-electric power which is devoted to municipal purposes is wasted; wasted, because not

utilized. And it is wasted irretrievably; it is not a resource which, like the natural fuels, if not utilized today is saved for tomorrow. It *might* have been utilized, and by its utilization have saved a corresponding amount of exhaustible fuel. This makes the crime a double one, one of omission and one of commission. The only possible excuse for the consumption of hydro-electric power in municipal and similar service is the lack of a market with better load factor. Such a market is furnished in an ideal form by the electrochemical industries, which can be so run as to have a load factor of from 95 to 100 per cent.

In view of the power famine in the Niagara district, Secretary Stimson will hardly offer this excuse, however, for his astonishing proposal. Ignorance of the elementary engineering proposition which we have pointed out above is almost inconceivable in one who has at his disposal the advice of the Engineering Corps, unless, perhaps, the natural activities of the Department of War, dealing as they do with destruction and, in a minor degree, with construction, are unfavorable to considerations of mere conservation. We are reluctantly forced to the conclusion that, in making the suggestion, Secretary Stimson was influenced, probably against his better judgment, by the unreasoning clamor of ill-informed persons whose prejudiced vociferations have done so much in recent years to retard, against every principle of conservation, the development of this great branch of the country's resources.

The conservation of our exhaustible supplies of natural fuels demands the development of the water powers of America, and every attention should be paid to their efficient utilization, not merely in relation to efficiency of power production, but particularly in relation to the even more important matter of efficient consumption in respect of load factor. It is becoming increasingly evident that the political and professional advocates of conservation cannot be trusted, either because of their ignorance or because of their prejudice, with questions of water-power policy; and the engineering professions and technical press will fail in their duty if they do not supply this deficiency by furnishing persistent instruction and criticism.

Pumping Slime with the Air-Lift

The growing popularity of the air-lift for transferring slime in connection with the cyanide process, calls to mind the fact that data and information pertaining to that operation are comparatively meagre. As a water pump the air-lift has been the subject of several investigations, with the result that definite conclusions have been announced as to its advantages and disadvantages, efficiency and essential features of design. The adaptation of the air-lift to slime pumping has been based largely on the data derived from water pumping, and in this respect it is probable that no serious error has been committed. Nevertheless, the idea suggests itself that a mechanical investigation of the air-lift as a slime pump would be valuable to the metallurgical engineer.

It is true that such data of operation as air and power consumption can be obtained from individual sources, but usually they refer to the performance of particular pumps which may or may not be well designed or operating under

favorable conditions. In any event they are not comprehensive enough to form a basis for conclusions. An independent experimental investigation ought to develop such data as are not likely to be brought out in practice, and determine relations having a direct bearing on correct design and operation. There are five variables which may affect a particular size and type of air-lift: submergence, lift, discharge, volume and pressure of air. To test various combinations of these variables involves a vast amount of work, but some interesting and valuable data would result.

It is unlikely that the efficient percentage of submergence in pumping slime would vary greatly from that determined for pumping water, namely, 63 per cent; but there are other relations in which the denser medium would make a difference. The coefficient of pipe friction and slip; the quantity of air for maximum discharge; the ratio of volume of air to volume of slime; maximum output; efficiency and input, and other points which could be determined experimentally under varying conditions of submergence and lift, would form a basis for intelligent design and operation of air-lifts for slime. No harm would result if several such investigations should be undertaken at the same time by different parties; on the contrary, the possibility of having several sets of data for comparison would be rather attractive.

Requirements for Successful Ore-Flotation

Signs of the times in metallurgy point toward a wider adoption of flotation in copper and zinc-lead concentration in the United States. This form of concentration, developed to its highest state of perfection in Australia, and widely used there in the treatment of zinc-lead ores, has been the subject of widespread experimentation during the past year. Two notable installations have been made in the western hemisphere; one at the Braden copper mines in South America, and the other at the Butte & Superior zinc mines in Montana. Experimental plants have been built and used at several places, and many ores have been tested. The success which has attended these first efforts evidently has influenced the management of the Miami and Inspiration copper companies in Arizona to delay completion of plans for remodeling the first-named mill and constructing the second, until tests can be made to determine the possible value of flotation in the treatment of their ores. The Federal company in Idaho also is reported to be experimenting with the process on zinc-lead ores.

The requirements for successful ore-flotation have been pretty well determined, and those who contemplate experimenting with the process should inform themselves on these points before proceeding further. Decomposed, oxidized ore, in general, seems to exert a deleterious effect, forming no "froth" and yielding poor results. Clean sulphide minerals are most favorable and give good results. Close sizing seems to be a prerequisite, for large particles of mineral in an unsized feed show a tendency to fall through the scum of floating concentrate, and in so doing they not only pass into the tailing, but carry finer mineral with them. This fact suggests a maximum size of particle, which should be determined by experiment.

The process further requires uniform conditions in the feed, and in the speed of the flotation machine. Irregular

quantity of feed disturbs the operation and causes loss of mineral. Fluctuation in the speed likewise has a bad effect and should be overcome by providing an independent source of power. The supply of oil should be constant. Not the least important factor is the consistency of the feed. Australian practice has developed a ratio of water to solids of 3 or 4 to 1. In some cases a thicker pulp has been used, but more dilute pulps are not advantageous.

The excellent paper by Mr. H. Hardy Smith, presented before the Australasian Institute of Mining Engineers and published in this issue, may be recommended to the careful attention of all interested engineers as one of the most valuable contributions to the literature on flotation.

Nichols-Hesse Dinner

Those who attended the International Congress of Applied Chemistry last year in New York City will certainly be delighted to hear of a movement to show the appreciation of their fellow chemists to the two men who bore the brunt of the battle—the President of the Congress, Dr. William H. Nichols, and the Secretary, Dr. B. C. Hesse. This mark of the appreciation of their work will take the form of a complimentary dinner, to be held at the Chemists' Club on April, 1912. It is particularly pleasant that this decision should have been reached by the joint unanimous action of the executive officials of the various chemical societies. Without doubt the rank and file of American chemists will join to make the dinner a brilliant success.

Can the Bessemer Steel Industry Be Saved?

It is an interesting fact that there has been no important improvement in the quality of Bessemer steel since the early years of the industry, now more than half a century old. Improvements in processes have been made, but they have conduced to lower costs rather than improved quality. Nothing could be much more beautiful, from an economic standpoint, than the method by which molten pig iron at a red heat is converted in a few minutes into molten steel at a white heat, yet all the trends of the times were apparently in recent years dooming this industry to eventual extinction. The United States saw its maximum production of Bessemer steel as far back as in 1906, whereas the iron industry as a whole has so grown meanwhile that pig iron is being produced at a rate 30 per cent greater than in 1906. In one product after another Bessemer steel has become unacceptable. Producers assert that in many cases the preference expressed by buyers for open-hearth steel is unreasonable, but they do not take steps to correct what they denominate a misconception.

The failure of Bessemer steel to equal open-hearth steel in quality is a failure under unfortunate circumstances, for the raw material of the Bessemer process is by far the purer. Two facts plead that someone should save the Bessemer process, one being that the United States possesses reserves of hundreds of millions of tons of relatively pure iron ore, within the Bessemer limit as to phosphorus, while the other is that in many cases, particularly the rolling of sheets, the drawing of wire and the threading of pipe, Bessemer steel yields itself more readily to the mechanical operation than does open hearth steel.

Two losses confront the industry. One is, perhaps, only a paper loss, covering the greater value which a few years ago Bessemer ores lying in the ground were held to possess over non-Bessemer ores, apart from the difference in average iron content, while the other lies in actual equipment which is being rendered less useful. The loss is not merely in Bessemer vessel capacity, and indeed that has been saved in some instances by the adoption of the duplex process, but covers also the complete rearrangement of works, if open-hearth is to be substituted for Bessemer, by reason of the much greater ground space required by open-hearth furnaces of equal tonnage output.

There is no doubt that Bessemer steel possesses certain valuable qualities as compared with open-hearth, even though they cannot all be measured quantitatively, and Bessemer steel, merely shorn of certain objectionable qualities, would undoubtedly prove superior to open-hearth for many uses involving an enormous tonnage.

We have expressed the opinion before that the savior of the Bessemer converter industry will be the electric refining furnace, and nothing has happened that would induce us to change this opinion. The refining of molten Bessemer metal in the electric furnace will undoubtedly solve all technical problems, in as much as it will yield a metal that should satisfy all requirements. The reason why the industrial development of the addition of electric refining furnaces to existing Bessemer plants has been so very slow is a commercial one and a perfectly natural one. It concerns both the steel consumer and producer and has to do in both cases with the question of cost.

In the case of the consumer, the railroad companies naturally hesitate to pay a higher price for rails made from electrically refined steel, until the evidence of the superiority of the "electric steel rail" is complete. Now this complete evidence can only come from the experience with electric steel rails in the track for a series of years. That is a safe and sane, but naturally very slow development. Last May Mr. William R. Walker stated officially for the U. S. Steel Corporation before the American Iron and Steel Institute that at that time approximately 5600 tons of standard electric steel rails were in service in the United States and had then been in the track about two years, being exposed at times to severest weather conditions and to all the possible conditions of severe service, and that up to that time they had not heard of any basic electric rails in use in this country being broken in service. It is a pleasure now to say here that what was true then holds good now.

As to the producer, the attempts are being continued to reduce the additional cost of electric refining as much as possible. And this again is essentially a slow process, as it involves a lot of experimental work both as to the best division of the metallurgical reactions between converter and electric furnace and as to administrative measures and arrangement of plant. The goal is to get the cost of combined converter and electric furnace process down to the cost of the open-hearth. There is every reason to expect that this goal will be reached. When this is accomplished, it is evident that the Bessemer converter industry has been saved.

Readers' Views and Comments

The Tungsten-Molybdenum Couple

To the Editor of Metallurgical and Chemical Engineering:

Sir:—I have read with great interest Dr. Northrup's article on the tungsten-molybdenum thermocouple in your January issue, page 45, and also the discussions of Drs. Hering and Thwing on pages 66 and 67 of the February issue. It may interest these gentlemen to hear that the tungsten-molybdenum couple was announced three months before the meeting of the Philadelphia branch of the A. I. E. E. referred to by Dr. Hering.

My Congress paper on the "Applications of Ductile Tungsten" was reported in abstract in the September 12, 1912, number of this journal, page 580. It is interesting to note that our value for the maximum point is 540 deg., compared to 530 deg. reported by Dr. Northrup.

Conservation and the Wastage at Niagara

To the Editor of Metallurgical and Chemical Engineering:

Sir:—With reference to recent articles in your journal on conservation and the wastage at Niagara, I send you the following verses, which were submitted to the *Outlook* five years ago.

It was my idea that the *Outlook's* views on conservation and on industrial democracy would naturally make the lines acceptable.

They were promptly declined.

Niagara Captive

Niagara captive! And by ribbons led!
His mighty force with that of toiling head
And hand to join. So changed since ancient days
When red men chanted hymns of praise;
In flower-laden white canoe
Each spring their fairest maiden sent into
The Thunder of the Waters.

Niagara an adult and to Effort bred—
No more to play the livelong day,
But proudly share the sweat and grime
Of stalwart manhood's laboring prime.
The evergrowing purpose runs:—
Earth's wealth is measured, not the sun's;
The stewards of great treasure may
Not waste Tomorrow's dire need
For Pleasure's or for Profit's greed.

Oh, Hercules, still at thy labors keep!
Canst take the raging current from the flood
And swiftly, silent 'round a cable sweep?
Ye Seven Wonders of the ancient world,
Long since into oblivion hurled,
Your kings and gods born to commemorate—
'Tis to the people do we dedicate
The Wonders of Today

Buffalo, N. Y.

EDWARD ZAREMBA

Early Mining Schools in America

To the Editor of Metallurgical and Chemical Engineering:

Sir On p. 114 of your February issue occurs the following misstatement: "George A. Koenig * * * at the University of Pennsylvania gave the first course of mining that was ever given in any educational institution in the United States."

Professor Koenig joined the faculty of the University of

Pennsylvania in 1872, and by 1871 six educational institutions had already graduated classes in mining. The first classes in mining graduated at Columbia in 1867, and at the University of Michigan the same year, Massachusetts Institute of Technology in 1868, Washington and Lee in 1869, and Lehigh and Lafayette each in 1871. Among these early graduates were some of the most distinguished men in the mining profession.

A course in mining was also started at Rensselaer Polytechnic Institute in 1867, but it was abandoned in 1871 for lack of funds.

Who first taught a course in mining in the United States would probably be difficult to determine, for undoubtedly rudimentary courses in the art were given long before schools of mining engineering were organized, but certainly it long antedated Professor Koenig's day.

EX-PROFESSOR.

San Francisco, Calif.

Corrosion and Immersion Tests on Metals

To the Editor of Metallurgical and Chemical Engineering:

Sir:—It has been customary for years and there seems to be no inclination to depart from the custom of giving the results on corrosion and immersion tests in terms of percentage loss by weight.

This is obviously not good practice as two results are not at all comparable unless the ratio of the weight to the surface exposed is the same in both cases.

If a 1-inch solid cube of steel is immersed in a 10 per cent. solution of sulphuric acid for 10 hours and a 1-inch hollow cube of the same steel is immersed for the same length of time the actual loss in weight should be presumably the same and on calculating the percentage loss by weight as is customary, the results would be entirely different and erroneous.

The foregoing is given as an illustration and is perhaps exaggerated but illustrates the point.

The writer has adopted the plan of giving the loss in grams per square inch of surface exposed.

If it is desirable to adhere to the metric system grams per square centimeter can be given.

There is, of course, the factor of time and to compare two results the time must be equal. Unfortunately the results of several hours cannot be reduced to a unit, say the hour, as corrosion or dissolution does not proceed at a uniform rate. It would be well for investigations to adopt some standard as to time and I would suggest one day (24 hours), 7 days and 28 days as being reasonable.

Other factors of importance are:

(a) The metal should always be tested with the same acid or substance for which the metal is intended.

(b) The ratio of the acid to the test piece should be the same in comparative tests as where this is different one becomes neutralized more quickly than the other. A rule could be established whereby a definite number of cubic centimeters of the acid could be taken for each square inch of surface exposed on the test piece.

(c) A separate receptacle should be had for each test piece. Should two test pieces of different metals be placed in the same bath electrolytic action may set up and cause dissolution to proceed more rapidly than otherwise.

(d) The temperature of the bath should be equal on comparative tests.

(e) In reporting results it should be stated whether the test piece was cast and machined, cast without machining, rolled or forged, etc.

Henry Clay, Del.

CHARLES E. ARNOLD.

The Solubility of Alumina in a Bath of Fused Fluorides

To the Editor of Metallurgical and Chemical Engineering:

Sir:—As the following data were unknown to several men most prominently connected with the development of the aluminium industry when told them after the symposium on alumina held at the recent meeting of the New York section of the American Electrochemical Society and were found only recently by me in some casual reading, their reproduction may be of interest.

Déville¹, in a Memoir on Silicium, after giving the results of other methods of isolating that element says:

"Finally silicium may also be extracted from silica by means of the battery—an exceedingly simple process which may also be utilized for the electrolysis of all substances which dissolve under heat in the fluorides of the alkalis—and these substances are very numerous. A mixture is made of sodium and potassium fluorides in about equal proportions which are melted together above a double current burner fed by alcohol to which turpentine is added and aided by a blow-pipe. When the material is fully fused, calcined silica is fed in which quickly dissolves. Then, putting the platinum and carbon poles of a Bunsen battery of four cells in the crucible, silicium is seen to deposit on the negative pole and oxygen is evolved at the positive pole. I have most frequently been satisfied to verify the decomposition of silica by the battery by this experiment, in using, as negative electrode, a platinum wire which was transformed with great ease into a fusible silicide.

"I desired to generalize this method in applying it to very different materials which are soluble in the fluorides, first of all to isolate the elements by the battery, and then to determine their position in the electrochemical series. Thus one can deduce from the experiment which I have just described that silica separates into its elements before soda and potash, and in consequence that silica should be decomposed by the alkali metals, which is indeed the fact. But if for silica alumina is substituted, the decomposition by the battery, in the midst of the alkali fluorides, would be effected in quite different order. One obtains as a matter of fact, at the negative pole, sodium which burns with a yellow flame, and at the positive pole, fluorine, which is immediately converted into hydrofluoric acid readily recognized by its odor. Alumina, therefore behaves quite differently from silica, and one must admit that it is not decomposed by the alkali metals, which all the attempts that have been made to obtain this reduction directly seem to have already shown."

In the light of subsequent events it is curious to note how close Déville, to whom we owe the first industrial isolation of aluminium, was, in 1857 to the winning of aluminium by means of electrolysis.

I had been successful there was no cheap current available. It is also interesting to note that this was not an haphazard experiment but one undertaken with a view to generalizing. It is true that soda and potash should be decomposed more readily by the current than alumina, but the alumina should have been decomposed more readily than the fluorides, and no doubt would have been if the proportions had been propitious.

New York City.

CHARLES A. DOREMUS.

Nitrogen, Its Influence in Steel

To the Editor of Metallurgical and Chemical Engineering:

Sir:—As several articles have recently appeared in the various technical journals relative to the momentous influence that small amounts of nitrogen may have in steel, and as various papers have been read on this subject before the engineering and chemical societies, the writer is led to relate the following from his experience and investigations dealing with the influence of this element in open-hearth and electric-furnace steels met with in every day practice, and of the grades used for small shafts, spindles, pneumatic tools, forming dies, etc.

¹Memoir on Silicium, *Annales de Chimie et de Physique*, 3, XLIX, p. 69, 1857.

In the main it may be conceded that nitrogen produces brittleness in all grades of steel though whether this element is itself the cause or whether its influence on other injurious elements, such as sulphur and phosphorus, in conjunction with it is the cause of brittleness, has not been satisfactorily determined.

It will require numerous tests, in view of the fact that practically similar conditions give inconsistent results, in which careful and complete analysis of a great many steels are compared with their physical properties to arrive at definite conclusions. It must be admitted, in general, that the results already obtained show practically no difference in the merits or demerits of steels that have been examined unless the phosphorus and nitrogen contents were abnormally high.

From the fact that metallurgists in common are at variance as to the proper methods for measuring the quality, or merits, of steel and from the uniformity of the merit formulae and figures, it is almost impossible to adopt a rule covering all conditions of comparison.

Mr. C. E. Stromeyer, in a paper read before the Institute of Naval Architects, London, England, gives the following rule for determining the quality, or merit, of steels from the phosphorus and nitrogen contents:

"The sum of the percentage of phosphorus plus five times the percentage of nitrogen should not exceed 0.080 per cent in good quality steel."

He further states, "that nitrogen has a ten fold greater effect than phosphorus in raising the tenacity of steel."

The formula most commonly used in England for determining the quality or merit of steels from their physical properties, elongation and tensile strength alone being considered as elastic limit and reduction of area are not factors, is as follows:

"M" = "T" + "E",

"M" = merit,

"T" = tensile strength in gross tons

"E" = elongation in per cent.

If tensile strength and elongation are directly or indirectly a measure of toughness, or the combination of ductility and toughness and ductility or toughness are the opposite qualities of brittleness, then a comparison of results determined from formulae combining tensile strength and elongation, and formulae showing the effects of nitrogen, should give conclusive evidence relative to the influence of the element nitrogen.

The following table gives the complete analyses, including nitrogen, of a number of steels that were investigated by the writer to determine the influence of the nitrogen present:

TABLE No. 1. COMPLETE ANALYSIS OF SAMPLES

Test Num- ber	Carb- on	Sili- con	Man- gan- ese	Sul- phur	Phos- phorus	Titan- ium	Chro- mium	Van- adium	Nitro- gen	Dupli- cate Anal- yses
1	.84	17	29	.009	.011				.12	0.10
2	.18	20	.40	.022	.013	.080			.08	.08

4	1.28	18	.37	.009	.013				.08	.060
5	.64	12	.25	.022	.018	.010			.10	.08
6	.48	20	.40	.012	.08			.20	.08	.14
7										

Note: Determined by

Summary.

No. 1—Average of nine Electric-furnace heats.

No. 2—One Electric-furnace heat to which .50 per cent Ferr. Testum was added.

No. 3—One Electric-furnace heat to which .30 per cent Rutile (1.5% of Titanium) was added.

No. 4—One Electric-furnace heat to which .60 per cent Rutile was added.

No. 5—Average of nine open-hearth furnace heats.

No. 6—One heat of Chrome-Yanawara steel.

No. 7—Drillings from Bessemer steel (20% of Nitrogen determined).

The method used for determining the nitrogen in these steels is as follows:

An Erlenmeyer flask of about 750 c.c. capacity is provided with a rubber stopper which carries a funnel and tube connected to a Bunsen condenser. The funnel is provided with a suitable stop cock.

About 500 c.c. of water, to which has been added .30 c.c. of

a solution of caustic soda equal in strength to hydrochloric acid of specific gravity 1.12 are put in the flask and boiled. During this preliminary boiling one gramme of the sample steel is dissolved in 20 c.c. of hydrochloric acid and this solution is then put in the funnel of the Erlenmeyer flask from which it is allowed to fall, drop by drop, by means of the stop cock in the boiling alkali solution, and distillation is continued until all the ammonia is driven over. The distillate is collected in graduated glass cylinders after which it is treated with Nessler's reagent and the coloration produced matched with standard solution of ammonium chloride.

The standard solution is made up of a strength equal to 0.03815 gram ammonium chloride per liter so that one c.c. is equivalent to 0.01 milligram of nitrogen.

It is, of course absolutely necessary in determinations of this kind to take extreme care that the water, hydrochloric acid, etc., used are perfectly free from nitrogen compounds.

The table below shows the physical properties of these steels together with a column of merits obtained from the English formulas given above.

TABLE NO. 2—PHYSICAL PROPERTIES OF SAMPLES

Test Number	Elastic Limit, Pounds	Tensile Strength, Pounds	Elongation, Per Cent	Reduction of Area, Per Cent	Merit
1	68,000	105,500	18.5	46	65.5
2	58,400	98,400	19.5	52	63.5
3	69,500	105,000	21.5	42	68.5
4	70,400	108,900	17.5	41	66.5
5	53,700	95,200	17	34.5	60
6	82,000	123,500	19	45.5	74
7			Not determined		

The steels containing titanium are especially given as the addition of this element is considered to retard the segregation of sulphur, phosphorus and carbon present; also, by its action in reducing a part of the nitrogen, it decreases brittleness and augments toughness and ductility. Its influence is said to be similar to manganese in reducing oxygen and in addition combines directly with nitrogen.

A lengthy paper on this subject by P. H. Dudley will be found in the *Journal of Ind. and Eng. Chemistry*, volume 3, pages 299 to 304.

In the heats referred to, the titanium was added as the steel was being poured into the ladle. In sample No. 2, 0.50 per cent, by weight, of ferro-titanium was added; this heat shows 0.080 per cent of titanium in the steel. Sample No. 3 about 0.30 per cent of titanium, by weight, was added in the form of rutile (red oxide of titanium ore); it will be observed in this case that the steel only shows a trace of titanium. It may be possible in this and, also, in sample No. 4, that the rutile added, being in fine powder and of light weight, floated on the surface of the molten steel and combined directly with the slag. In sample No. 4 about 0.60 per cent titanium was added in the form of rutile.

If we now apply Mr. Stromeyer's rule for quality judged from the phosphorus and nitrogen contents and assume the factor of P plus 5 (nitrogen) should not exceed 0.080 per cent, we get figures as follows:

Sample.	P + 5 (Nit.).	Merit.
1	.060	18.75
2	.053	33.75
3	.079	1.25
4	.068	15.00
5	.033	58.75
6	.038	52.50
7	Not determined.	

The merits obtained from the physical properties indicate sample No. 3 as being the next to the best steel, while from the P plus 5 (Nit.) formulae it is placed as last in rank, in fact it is very close to the danger point. This is only another case of the inconsistency or disagreement of merit figures. Sample No. 4 is third highest from its physical properties and is next to the last merit from its phosphorus and nitrogen contents.

Sample No. 6, which is an extremely good steel as indicated by its physical properties, also excels in merit from its nitrogen and phosphorus contents; it will be observed that it is very low in both these elements.

The average of the open-hearth heats, sample No. 5, are extremely low in nitrogen; the physical properties are, also, good for this class of steel. These steels were made in a basic furnace and are far superior to the rail steel given as sample No. 7 if the elimination of nitrogen is a criterion. The functions leading to superiority of basic open-hearth steels are the possibilities for the elimination of sulphur and phosphorus and the reduction of the oxides. In this case extreme care in operation was taken; the quality of the steel produced shows the effects of this careful handling.

The writer trusts the merits and demerits of nitrogen in steel will be discussed further or until a definite and clear understanding of its effects on the quality of all grades of steel shall be firmly established.

E. D. A.

The Western Metallurgical Field

Proposed Merger at Cripple Creek

Considerable interest attaches to the recent examination of the Golden Cycle mine in the Cripple Creek district by Mr. Richard A. Parker on behalf of the El Paso company. It is currently reported that Mr. Allen L. Burris, president of the El Paso, has been making an effort to consolidate some Cripple Creek mines, together with the district railroads, and that Golden Cycle mines and cyanide mill are part of the merger. A \$25,000,000 holding corporation is part of the announced plan, and the properties to be acquired are the following: Golden Cycle mines and cyanide mill, El Paso mines, Colorado Springs & Cripple Creek District Railway, Midland Terminal Railway, Florence & Cripple Creek Railway, Gold Belt Railway, and the High and Low electric lines. The holding company will engage in general mining business, confining its activities to the Cripple Creek district for the present.

Copper Smelting in Michigan

Smelting practice in the Michigan copper district does not vary materially at the different smelters. The process is practically one of melting and refining, as the concentrates are mostly metal. At the Quincy smelter the concentrates are separated into three grades: No. 0, mass, containing from 65 to 70 per cent copper; No. 1, coarse concentrate and some mortar discharge, averaging about 75 per cent copper; No. 2, fine concentrate, containing from 10 to 25 per cent copper. The poorest grade, No. 2, is agglomerated in a reverberatory furnace and later smelted in a blast furnace. This practice has superseded the former method of briquetting the fine copper for blast furnace reduction. No. 0 and 1 grades are melted in reverberatory furnaces having a capacity of about 50,000 lb, refined copper. The operation is intermittent, covering the following operations: The furnace is charged at 4 p. m., and the charge is skimmed every two hours after slag begins to form. This melting and skimming is continued for 15 hours, after which the charge is refined with air, oxidizing arsenic and other impurities, and forming some copper oxide. The molten bath at this stage contains about 95 per cent metal and 5 per cent oxide. The latter is then reduced by poling and with charcoal. Casting is commenced about 1 p. m. and finished about 3 p. m. The furnace is repaired if necessary and made ready for the next charge at 4 p. m.

Casting at the Quincy smelter is done by hand from ladles that are carried on an overhead track that runs above the line of molds. At the Michigan smelter a Walker casting wheel is in use, and at the Calumet & Hecla similar wheels are used in connection with two new reverberatory furnaces. The latter have capacities of 125,000 lb. of refined copper per day each, and are equipped with Stirling boilers for generating steam from waste heat, after the manner of similar equipment on reverberatory furnaces in the western copper smelters. There are some objections to the use of casting wheels; the cast

copper cools quickly, but if the wheel is moved before the surface is set, the ingots have a rough, wavy surface which is objectionable in subsequent rolling for industrial uses.

Reverberatory slags are high in copper, but if lower-grade slags were made it would be at the expense of the grade of metal produced; and as the slags would have to be resmelted in any event, there is no object in trying to get them as low as possible. Such slags will carry from 10 to 12 per cent copper, and are richer in metal toward the end of the skimming process. They are smelted in a low-pressure blast furnace, the product of which is copper of 95 per cent purity, which is later refined in a reverberatory. Slag runs continuously from the blast furnace, carrying about 0.8 per cent copper, which is about twice the grade of slags from western matte furnaces. Lower-grade slags involve reduction of iron which contaminates the copper. The principal flux used in the blast furnace is limestone, although iron in the form of pyrites cinder is used on occasion. Anthracite coal is preferred to coke, the latter being used when the furnace shows signs of running cold, or when accretions build up in the shaft.

Company Reports

The *Shannon Copper Company* has just issued a report covering the operations during the last four months of 1912. The company treated 95,235 tons of its own ore, producing 5,149,805 lb. copper, 1012 oz. gold and 54,394 oz. silver. The cost per lb. copper during the four months was as follows:

September	13.858 cents.
October	14.837 "
November	12.714 "
December	12.548 "

The high costs during this period were due to charging off certain increases in taxes and liability insurance which the legislature enacted last summer, and which could not be distributed over the costs for the year. Another cause contributing to high cost was the chilling of the large furnace during October, reducing production for several days without reducing expenses. The net profits for the period were as follows:

	Mines.	Railroad.	Total.
September	\$41,000	\$1,415	\$42,415
October	29,000	1,039	30,039
November	66,200	1,850	68,050
December	65,695	1,773	67,468

The report states that the mines are in better condition than for years, and the lower levels hold out better promise than ever before. Dividends amounting to \$300,000 were paid during the last eight months of the year.

The *Nevada Consolidated Copper Company's* report for the last quarter of 1912 shows a marked decrease in production compared with the preceding quarters, owing to labor difficulties which caused a complete suspension of operations from October 2 to October 24. The grade of ore milled, 1.44 per cent copper, was lower than usual. The production of copper was only 8,986,905 lb., less than half the usual production.

The reports of the *Utah Copper Company*, covering the fourth quarter of 1912, shows a monthly production of 4,302,194 lb. copper as compared with an average of twice that figure for the preceding months of the year. The decrease is ascribed to labor troubles, referred to in the last quarterly report, and to the shortage of labor caused by the emigration of foreign laborers for service in the Balkan War. The average assay of ore treated during the quarter was 1.104 per cent copper, as compared with 1.41 per cent for the preceding quarter. The average cost of copper, after making allowances for smelter deductions was 14.83 cents per pound, compared with 7.57 cents for the preceding quarter. The high cost was due to deficiency in tonnage, low grade of ore and extraordinary expenses. On the date of the report, Feb. 1, the mills were treating 18,000 tons per day, and it was expected that within thirty days the full capacity of 20,000 tons daily would again be reached.

The nineteenth annual report of the *Portland Gold Mining Company*, Cripple Creek district, Colorado, was issued on Feb-

ruary 3, and shows the company to be in excellent condition, with greatly improved metallurgical facilities. The Colorado Springs mill has been reconstructed into an up-to-date cyanide mill, and has been operating at its full capacity of 400 tons per day since November 15, 1912. The new mill at Victor has continued to demonstrate its success in treating low grade ore which formerly was thrown on the dump as waste. Its capacity has been increased from 12,285 tons treated in December, 1911, to 14,791 tons in December, 1912. Additions have been made to increase the concentrating capacity, consisting of twelve concentrating tables. Further additions to plant consisted of four Pachuca tanks, one Dorr thickener and two classifiers. These changes have raised the original capacity of the mill from 300 tons per day to 500 tons. It is expected that the net profits from this mill will be equal to the dividend requirements of the company, leaving the profits from the old mill to be applied toward building up a substantial reserve fund. The average value per ton of ore treated in the new mill was \$3.15, yielding a net profit of \$1.17 per ton. The profits earned by this mill in 1911 and 1912 have equaled 90 per cent of its cost, and only a beginning has been made toward the treatment of the vast tonnage of low-grade ore available. The Cripple Creek drainage tunnel has lowered the water in the Portland mines 207 ft., and mining operations are now conducted on the sixteenth level, where the ore bodies are larger than above. All pending litigation has been compromised. The total net profits for the year were \$325,507.84; dividends for the year, \$240,000, and for the entire history of the company, \$9,157,080.

Rochester, Nevada

The newest mining camp in Nevada which is attracting more than usual attention, is Rochester, in the Humboldt mountains, Humboldt county, being east of Oriana and Lovelock, which are on the Southern Pacific railroad. An incipient boom is now under way, and the prospect is that by late spring or early summer a new mining district will be well organized. New discoveries of high-grade silver ore have revived interest in a district which was active in the early sixties, when rich refractory ore was shipped from there to Swansea, Wales, for reduction. The ore now being mined resembles that of Tonopah, being high grade in silver and low in gold. At present two mines are shipping about 20 tons of ore daily to the Mason Valley smelter at Thompson, Nevada. A great deal of development work is being done, and some sales of property are being made. Approximately 2000 people are in camp, and more are coming in daily. The winter weather is reported to be favorable to prospecting. Owners of prospects for sale are much more conservative in their demands than they have been in other Nevada camps, and indications are that outside capital will be encouraged to come in. An element of permanency is found in the construction of a steam-electric power plant at Oriana, 10 miles distant, to transmit power to the mines. At present all mining is done by hand-drilling, and as the rock is extremely hard, little progress can be made.

Organizations of Mining Men

Matters of state and national legislation affecting the mining industry are resulting in the organization of mining men in different parts of the country. The question of mine taxation is the foremost issue in the different states, while the tariff on lead and zinc is the national issue around which much discussion is being waged.

The subject of taxation is before the legislatures of Utah and Colorado, and new organizations have been effected in both states to see that no unwise measures are passed. The principles of mine taxation unquestionably are not yet settled to the satisfaction of mine owners, nor is there any uniformity in the laws in different mining states. This state of affairs has received the attention of the American Mining Congress which, at its last session in Spokane, passed a resolution appointing a committee on mine taxation to report at the next session of the congress. In the meantime Colorado proposes a law that shall assess mining property at its full cash value, directing assessors

to take into consideration any matters that will enable them to arrive at a fair and equitable cash valuation. Manifestly this means nothing, and points the way to the great need of a scientific method of arriving at the value of mining property. Such a method as Colorado proposes will result in confusion and dissatisfaction. It has been remarked before by competent engineers that foreign countries have solved this question more satisfactorily than we have; that distinction is made between idle and active owners; that the former are subject to more than nominal taxation, and that output is taken as a basis for the taxation of active companies. It is to be hoped that our own states will accomplish something constructive and sound along this line, for many instances might be cited in which the question of unscientific taxation determines the difference between idleness and activity of some companies.

The proposed reductions of the tariff on lead and zinc are being vigorously opposed by the American Mining Congress under the active direction of the secretary, James F. Callbreath, who is at Washington. He has been well supported by representatives from Missouri, but assistance from other states has not been as vigorous as is desired. If the question has vital interest to producers of these metals, there seems to be a strange apathy among many of them.

Iron and Steel Market

The pressure upon steel mills for delivery of material showed no abatement in February. Demand against existing contracts continued strong, with specifications substantially equal to shipments, and efforts in many cases on the part of buyers to have shipments expedited against specifications already filed.

There have been no important advances or declines in the regular base prices of important finished steel products, and these prices are well maintained. There has been a very considerable reduction in the premiums paid for early delivery of certain products, also a diminution in the tonnage of material sold at premiums, so that the premium market is now relatively unimportant. Probably this change can properly be ascribed to the fact that we have been passing through the winter period.

In pig iron, which in recent years has presented a market altogether distinct from that of steel products, the slight weakening which occurred in January was carried farther. Pig iron prices no longer control steel prices, only a very small portion of the total merchant pig iron output being sold by direct barter with steel producers. Steel prices are affected only sentimentally, and then but very slightly.

Connellsville coke, which began to weaken late in January, slumped in the fore part of February, so that prompt furnace coke, which ruled at \$4.00 a ton or higher from the beginning of November until late in January, sold at as low as \$2.25, firming up slightly after considerable accumulations were liquidated, and making a market of \$2.40 to \$2.50 in the closing week of February. There being no important negotiations, a definite market for contract coke was not developed, but early in January it was impossible to contract for standard brands at less than about \$3.50, while by the middle of February it became evident that if buyers and sellers got together it would hardly be on a basis outside the limits of \$2.25 and \$2.50. The slump in coke was due to several influences. The market had become unreasonably high, both in relation to cost of manufacture and in relation to selling prices of pig iron and steel products. There were fears in November and early December of an actual famine later on, production being usually curtailed around the holidays through too strenuous celebration by the workmen, and also being usually subject to curtailment through bad weather. Stocks were accumulated against these probable contingencies, but the winter proving exceptionally open production was not curtailed through natural conditions and in January furnaces began to use up stocks. At the same time more than half a dozen steel works furnaces began to work badly and took reduced coke shipments. Production increased slightly, and the combination of circumstances, increased production and reduced demand, although

amounting to but a very small percentage of the total movement, was sufficient to change the complexion of the market completely. There is no permanent decrease in consumption, whereas with the freer supply furnaces will refuse to take the poor coke they willingly accepted in December and January, forcing restriction of output at the plants making poor coke, and this readjustment will probably hold coke at a moderately high level, though much below the unreasonably high level which recently prevailed.

Reports of business and financial activity outside the steel industry proper have been uniformly unfavorable, and it has been a surprise that the steel industry has not been affected. There are many who think it has been, evidently believing that unfavorable developments in the steel industry have been concealed. There is no reason to believe that their attitude is correct. The steel industry is in strong position, with a very large volume of sound business on books, and strictly new buying naturally light in consequence. The divergence between conditions in steel and in other branches of activity is explainable on the ground that the country has continued to develop steel requirements in recent years, while steel making and finishing capacity has increased very little in the past three or four years, in comparison with the rapid increase in demand in all previous time. This fact can readily be illustrated quantitatively.

In the decade ended with 1897 pig iron production increased 94 per cent. over the previous decade, and the next decade showed a further increase of 120 per cent., the average of these increases being 107 per cent. An increase of 107 per cent. over the 181,470,000 tons produced in the ten years ended with 1907 would require an output of 376,000,000 tons in the ten years to end with 1917. The five years of that period already elapsed have produced but 122,412,000 tons, leaving 254,000,000 tons for the five years 1913 to 1917 inclusive, whereas it is straining the industry's capacity at present to maintain a rate of a trifle over 33,000,000 tons. There are a few idle furnaces, but it would be impossible to swell the production rate to 35,000,000 tons a year and avoid loss to poorly positioned operations, unless finished products should advance more than raw materials and the alignment is such that this could not occur.

There is reason to conclude, therefore, that the steel industry remains active and in strong position when general business is not particularly good simply because, from a variety of influences, development of producing capacity has not kept pace with development of consuming capacity.

Pig Iron

Since its high point towards the close of December pig iron has declined an average of almost 50 cents a ton, the declines being practically uniform in foundry pig iron in all markets, but being very slight in steel making iron in the Pittsburgh valley district and in eastern Pennsylvania. The declines have occurred very quietly, in a dull and stagnant market, and it is likely that the development of a moderate demand would develop still lower, rather than higher prices. The practice of buyers of foundry iron is well known: on a rising market they buy farther and farther ahead, while given a weak market they refuse to buy until delivery has been completed on all their purchases. The furnaces are fully sold up for perhaps two or three months to come, and deliveries are being very well taken, so that iron is not accumulating, but it is fairly safe to predict that prices will continue soft until April or perhaps a later month, when the real test of the market will come. In the circumstances, it would not require an exceptionally heavy demand to stiffen prices again. The market now stands quotable as follows: Bessemer, \$17.25; basic, \$16.35; No. 2 foundry and malleable, \$17; forge, \$16.50, f.o.b. valley furnaces, 90 cents higher delivered Pittsburgh; No. 2X, delivered Philadelphia, \$18.25; No. 2, foundry, f.o.b. Buffalo furnaces, \$17; No. 2 foundry, f.o.b. Cleveland furnaces, \$16.50 to \$17; No. 2 foundry, f.o.b. Chicago furnaces, \$17.25; No. 2 foundry, Birmingham, \$13.50, with some resale iron offered at \$13.

Steel

Never, perhaps, have transactions in billets and sheet bars been so light. There has been practically no steel available for early shipment, and for such later shipment as the mills could compass they simply refuse to quote. As representing the general temper of the market we quote billets at \$29, sheet bars at \$30 and rods at \$30, f.o.b. maker's mill. Pittsburgh or Youngstown.

Finished Steel

Effective February 1, the National Tube Company advanced steel boiler tubes one point, or about \$2 a ton, other makers immediately concurring.

Regular prices at Pittsburgh, unless otherwise stated, are given below, subject in some cases to premiums for early delivery:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.45 cents.

Shapes, 1.50 cents.

Steel bars, 1.40 cents.

Steel hoops, 1.60 cents.

Common iron bars, 1.65 cents, Pittsburgh; 1.65 cents, Philadelphia; 1.60 cents, Chicago.

Sheets, blue annealed, 10 gage, 1.75 cents; black, 28 gage, 2.35 cents; galvanized, 28 gage, 3.50 cents; painted corrugated, 28 gage, 2.55 cents; galvanized corrugated, 3.55 cents.

Tin plates, \$3.60 for 100-pound cokes.

Merchant steel pipe, $\frac{3}{4}$ to 3-in., 80 per cent. off list.

Steel boiler tubes, $\frac{3}{4}$ to 4 $\frac{1}{2}$ -in., 70 per cent. off list.

Standard railroad spikes, 1.85 to 1.90 cents.

Button head structural rivets, 2.20 cents; cone head boiler rivets, 2.30 cents.

The price of 1.45 cents now quoted on plates and shapes is the price which the steel corporation has regularly maintained; for a time independent manufacturers endeavored to obtain 1.50 cents and as the steel corporation accepted only selected business at its quotation the market was quoted in general at 1.50 cents. As it is now recognized that the independents can book little attractive business at higher than 1.45 cents the general market is now quoted at that figure.

John Fritz

In John Fritz the engineering profession and the steel industry has lost a master mind, the United States one of its greatest citizens. A self-made man and a self-taught engineer he was a peer of the most eminent steel men of three generations and the engineering societies honored themselves when on the occasion of his 80th birthday they established the John Fritz medal to perpetuate the memory of his life work.

In view of the fact that he left for us to read his delightfully interesting autobiography there is no necessity here to go into details. Only a few dates and a few attainments shall be mentioned.

John Fritz was born Aug. 21, 1822, in Londonderry Township, Chester County, Pa. His early days were spent on a farm. At the age of fifteen he left school and became a blacksmith's apprentice. He became interested in foundry work, obtained employment with the Norristown Iron Works in 1845, and within a few months was superintendent of the plant. In 1849 he left this position and accepted one as mechanical engineer to put up the machinery for a rolling mill at Safe Harbor, Pa.

His health soon failed at Safe Harbor, and he was forced to leave. Then for several years he struggled with fever, working only a part of the time. His services were much sought, both at Safe Harbor and at Norristown.

In 1854 one of his former employers became interested in the Cambria Iron Works, at Johnstown, Pa., and induced Mr. Fritz to go there as general superintendent.

One of his innovations there was the replacing of the two-high rolls with three-high rolls, to effect greater economy and lessen the likelihood of accidents. This was made in 1857.

In 1860 he left the Cambria Iron Works and became general superintendent and chief engineer of the Bethlehem Iron Company, which was then about to build a plant at Bethlehem, Pa.

In 1864, the Bessemer process was introduced into the United States. Mr. Fritz had been studying the matter of steel-headed rails, and although the first steel rails in this country were failures, he induced his employers to build a Bessemer plant. Believing the failures were due to an unnecessary amount of phosphorus. The plant was started in 1868. About the same time the manufacture of acid open-hearth steel began, using the Siemens regenerating furnace. Three years later Mr. Fritz had a Siemens furnace installed at the Bethlehem plant, with important modifications of his own that proved successful.

The following year he added a blooming mill. He then turned his attention to the making of plates and structural shapes, but his company would not take up their manufacture. He later succeeded, however, in getting the company to install a forge and armor-plate plant, although there was at that time neither the demand for the thick steel plate nor proof that it could succeed. It did succeed in tests, and the demand was created.

Mr. Fritz retired from active work several years ago. Pre-

THE LATE JOHN FRITZ

vious to his death he had been in feeble health for more than a year. He died at his home in Bethlehem on February 13.

The funeral services were held at his late residence, which, though spacious, could not contain his many hundreds of friends, including eminent men of all callings and the delegations from the national societies. A special car brought engineers from New York, and there were present a large number of Lehigh University students. Thousands of the townspeople and steel plant employees waited patiently in the winter wind to follow "Uncle John Fritz" reverently a few hundred feet to his last resting place above the valley where the vast steel plant which is one of his enduring monuments extended for miles in unvoiced silence.

George W. Maynard

George W. Maynard, prominent as mining engineer and metallurgist and highly esteemed as a man by all who had the pleasure to know him, died in Boston on February 13, after an illness of several weeks which had started while he was on a professional mining trip to the West.

Mr. Maynard was born in Brooklyn, N. Y., on June 12, 1830. He graduated from Columbia as one of the famous class of 1860—the first class of the department of Chemistry at Columbia.

Last September (Vol. X, p. 517, 1912) it was the privilege of this journal to publish from Mr. Maynard's own pen rem-

iniscences of those earliest days of chemistry in New York City, together with the picture of the class of 1860 of the department of chemistry. Mr. Maynard wrote these reminiscences just before he started on his last trip to the West. They were his last contribution to literature and were characteristic of the man and his true big heart.

In 1860 he went to Germany and for a year studied chemistry, physics, and mineralogy in the University of Goettingen, under Woehler. While there he was a fellow student with J. Pierpont Morgan. Leaving Goettingen he spent a year at Clausthal in the Hartz Mountains with Bruno Kerl, studying mining and metallurgy in the School of Mines there. In 1862 he received the degree of Master of Arts from Columbia.

Mr. Maynard's professional practice started with an engagement at the Connoree mines in County Wicklow, Ireland, where he remained a year occupied in chemical and metallurgical work. In 1864 he returned to New York to establish an engineering office and chemical laboratory, and in the spring of the same year he made his first professional examination of a mining property in Colorado. He liked the West and in December, 1864, he returned to Colorado to establish an engineering office and assay laboratory in Gilpin County.

Mr. Maynard returned to New York in the winter of 1867, taking charge of a sulphuric-acid plant on Staten Island. In 1868 he was appointed Professor of mining and metallurgy at the Rensselaer Polytechnic Institute in Troy, N. Y., and occupied that chair until 1872. From 1873 to 1879 he was in Europe. His headquarters were in London, but during this time he spent six months in eastern Russia, erecting a copper reduction works for a British company at Voskresenky.

His stay in London became important for his future, as he was consulting engineer for several iron and steel works in England and Wales, and in such capacity made at Middlesbrough, England, the first demonstration in a large way of the basic Bessemer process of steel making. He was a very intimate friend of Sydney Gilchrist Thomas.

Mr. Maynard returned to New York in 1879 for the purpose of introducing the Thomas-Gilchrist process into the United States, and sold the patents to the Bessemer company, afterward known as the Steel Patents Company. Subsequent to that time Mr. Maynard always resided in this country, though he made various brief professional trips abroad.

Mr. Maynard continued his consulting practice until the time of his death. He died in the saddle. His many friends will remember him as a mining and metallurgical engineer of high attainments and as a man of lovable character.

Raphael H. Wolff

Raphael H. Wolff, widely known through his long connection with the iron and steel industries of both the United States and Germany and prominent through his great activity in introducing the electric steel furnace in this country, died on January 23 in a sanitarium in the Grunewald, near Berlin, Germany. Mr. Wolff had gone to Europe last June on one of his trips in which he used to combine rest and recreation with study of commercial and industrial conditions and none of the many friends who saw him off on that fine Saturday morning on the dock in Hoboken, could have imagined that it was a farewell forever.

Mr. Wolff came of an old family of wire manufacturers, with a mill at Neheim on the Ruhr in the Westphalian district. He came to the United States in 1870 and first found employment with the Pratt and Whitney Co., of Hartford.

Mr. Wolff was then for many years an importer of iron and steel in New York City, chiefly of wire rods and steel billets. Later he established a wire mill at 17th Street and the Harlem River, New York City, and conducted it as the head of the firm of R. H. Wolff & Company, Ltd. There he manufactured for many years cold rolled strip steel and high-grade wires, including piano wire and watch-spring steel ribbon. During the period of the bicycle craze he also took up the building of wheels.

Mr. Wolff sold his plant in 1902 to the Washburn Wire Company. He then became connected with the Crucible Steel Company of America. He became their European representative and established their European department with headquarters at Hamburg, Germany, and was soon successful in building up an important business.

Some ten years ago Mr. Wolff investigated for an American company the Heroult electric steel refining process and reported favorably on it, but his recommendations were not followed. It is a pity on account of the private character of this report that extracts from it cannot be given here, as that report was a model of business sagacity, proving that Mr. Wolff was one of the earliest practical iron and steel men who grasped the potentialities of electric refining.

As a result of his firm conviction in the great feature of the electric steel furnace Mr. Wolff became connected with Dr. Paul Heroult as his American representative and as such he developed an untiring activity in interesting the big men in the American iron and steel industry in the electric furnace. By word and by writing he conducted a persistent campaign for the Heroult electric steel furnace. His articles on the use of electric furnace for making alloy steels, on commercial electric steel and gas power and the possibilities of the electric

THE LATE R. H. WOLFF

furnace in steel foundry practice, on the electric furnace for rail and ordnance steel, published in this journal, volume 6, pages 6, 225, and 485 (1908) will even now repay rereading. He was one of the earliest men to recognize the importance of dividing properly the metallurgical reactions between the ordinary oxidizing furnace and the electric refining furnace so as to reduce the cost of electric refining. He took out a patent for a process the chief feature of which was to restrict the treatment in the electric furnace simply to the object of finishing and resting the metal so that any gas or slag left in the metal should rise to the top (this journal, volume 8, page 288, 1910).

Mr. Wolff conducted the negotiations which led to the installation of various Heroult electric furnaces in American steel plants and finally resulted in the acquisition of the American rights in the Heroult furnace by the United States Steel Corporation.

Mr. Wolff was also largely instrumental in the establishment of the ferro-silicon plant of Electro-Metals, Ltd., at Welland, Ontario. He was the president of this company for several years and was on its Board of Directors until the time of his death.

Mr. Wolff was a man of strictest business integrity, a man of strong character and a kind heart. His untimely death is mourned by many friends.

Pulverized Coal as a Fuel

By H. R. Barnhurst

Coal properly pulverized and burned may be made to yield higher economic results than are attainable by any other means.

The requirements necessary to success, while simple, are absolute and must be obeyed.

First—The coal must be dried so that it contains not over 1 per cent of moisture.

Second—The coal must be pulverized to a high degree of fineness.

Third—It must be projected into a chamber hot enough to cause instant deflagration.

Fourth—It must be supplied with air sufficient to yield the oxygen necessary to burn the carbon of the coal at once to CO_2 .

Taking up these requirements in order, the drying of the coal to a moisture content of not over 1 per cent is indispensable. Coal does not grind well if moisture in excess of this be present.

In burning coal the moisture, free or combined, must be disposed of either in the process of preparation or in the moment of combustion. In the latter case not only is the efficiency of the furnace lowered by the calorific investment in the superheated steam passing out as a product, but the temperature of the furnace is lowered materially. The drying of wet coal in the furnace itself, is doing this necessary part of the work in the most expensive place and at the cost of temperatures which may be essential to the industrial process of which high heat is a factor.

Fine grinding—With the best type of machines obtainable for this purpose, the coal and its contained impurities may readily be powdered to such a degree that under the screen tests 85 to 90 per cent will pass through apertures $1/400$ in. square, while the total residuum left upon a screen whose apertures are $1/200$ in. square, will be from $2\frac{1}{2}$ to 5 per cent and this residuum would pass through screens of $1/100$ in. square. It must, however, be borne in mind that of the percentage passing the smaller apertures $1/400$ in. square there is a high percentage of absolute dust or impalpable powder not commercially measurable. This is proven by the fact that in tests made upon calibrated screens of $1/600$ in. square apertures, over 70 per cent still passed through. It certainly appears to be safe to assume, therefore, that the average size of the particles would be below a cube measuring $1/600$ in. on the side.

It may be interesting, therefore, to state that the total numbers of particles resulting from the powdering of 1 cubic inch of coal to the dimensions given would yield 216,000,000 grains of dust. Simple calculation on this basis shows that while a cubic inch of coal exposes 6 square inches for the absorption and liberation of heat, the surface exposed for the same purposes by the powdered coal is 25 square feet. Inasmuch as no fuel burns until it is heated to a temperature at which it develops more heat than it receives, the advantage of this enormous absorbing and delivering surface is apparent. The result of this is shown in the clearness and uniformity of the flame produced. Where coarse particles are permitted to enter the furnace, the distinct sparkles are apparent. These larger particles are carried beyond the region of oxygen supply and are for this reason not fully burned.

Third—While coal ignites freely, in a hot chamber, this ignition means the absorption of heat from somewhere, and if the coal rapidly projected by air does not develop its heat near the point of ignition, means must be devised to maintain the heat necessary for ignition where it is needed, i. e. at the first entrance of the coal into the furnace. It is apparent, therefore, that giving the fuel too great velocity upon entrance is not good practice.

Considering the fourth requirement along with the third we would say that some singular errors and misconceptions have attended the practices of many users of powdered coal.

More particularly do we refer to the use of large fans to supply the air necessary for the projection of the fuel, where the air nozzle has been reduced from 16 in. or 18 in. diameter to 4 or 5 in. at the jet under the expectation that all of the air in the 16 in. or 18 in. pipe would be hurried through the 4 or 5 in. nozzle if not a smaller one. The futility of this is apparent.

To describe the operation more clearly, the coal is received in a bin over the feeders. (Fig. 1.) Its weight is about 38 lb. per cubic foot when loose in the bin. Settling awhile brings the weight to about 45 lb. per cubic foot by displacing the entrained air. Across the bottom of this bin and within a pipe extending horizontally from it is a double-flight worm or feed screw. This double-flight screw resists the tendency of the light coal to flow of itself along the feed pipe. This screw extends over a flanged pipe-cross into which the fuel is delivered. The rear end of the screw is supported by a bearing in a flange on the side of the bin near the bottom, the shaft projecting to receive a driving pulley or chain sprocket. The delivery end of the screw shaft is supported by a bearing in the cover of the horizontal opening of the flanged pipe-cross. The top opening of the cross is uncovered to permit the air

FIG. 1.—ARRANGEMENT OF PLANT FOR USING PULVERIZED COAL AS FUEL

to draw down with the falling fuel. This fuel dispersed in the air so drawn in, descends a vertical pipe attached to the lower opening of the cross, the pipe being long enough to be within the funnel or injection pipe. At the bottom of the funnel is a diagonal plate upon which the fuel falls. The plate is tight against the air pipe up the current and flared open on the side, towards the furnace down the current and takes up about one-fourth the diameter of the pipe. This forms at this point a "vena contracta" producing a suction in the funnel, drawing in through it, supplementary air with the fuel. The fuel spraying upon this plate mixes very thoroughly with the air from the fan, the eddy currents caused by it, assisting very materially its dispersal through the main column of air supplied by the fan.

The admission funnel should be far enough from the furnace to permit this mixture to be thorough. Too high pressures defeat this somewhat, as well as tending to project the fuel too far into the furnace before flashing. As soon as this fuel cloud begins to absorb the heat of the chamber into which it passes, a rapid expansion of the air takes place, separating the particles of fuel in suspension, in the proportions of the absolute temperatures to the temperature of the initial air. It is a matter of discussion whether the best results are obtainable by a delivery of all the air found necessary for combustion by the feed pipe together with the percentage of excess air found to produce the best results, or to use a smaller quantity of air in the feed pipe and look for the further supply from other openings.

Good practice would seem to point to absolute control of

air by the fan and its gates, and the fuel by the varied speed of the feed screw. The furnace should have a good natural draft to a chimney controlled by a damper. It must be remembered that perfect combustion of one pound of carbon demands 2 2/3 pounds of oxygen. This is contained in 11.6 pounds of air or about 15.4 cubic feet; should less than this be supplied a proportionate amount of fuel will be burned to CO with a loss of two-thirds of its initial efficiency, a part of which may be regained by contact with heated oxygen, or it may pass on and burn in the chimney, doing no good if the heated oxygen is brought there in first contact with it. If the oxygen is not heated sufficiently smoke will result and the full heat be undeveloped.

The greater the volatile constituents of the coal the more readily will it deflagrate, as these gases distil from the fuel and ignite at a temperature lower than that required for the carbon itself. Their need for oxygen is, however, greater per pound of fuel (or gases) than that of carbon, and is proportional to the heat evolved. Their average value is in heat units nearly 50 per cent more than that of carbon.

The temperatures attainable with pulverized coal are very high, so high that excess air is commonly admitted in proportions ranging between 50 and 100 per cent. This will be shown by the following table based upon the perfect theoretical combustion of carbon with proportion of air given:

1 lb. carbon with 11.6 lb. air.....	Normal.	4850° F.
1 lb. carbon with 12.76 lb. air.....	10 per cent excess.	4448° F.
1 lb. carbon with 13.92 lb. air.....	20 per cent excess.	4102° F.
1 lb. carbon with 15.08 lb. air.....	30 per cent excess.	3807° F.
1 lb. carbon with 16.24 lb. air.....	40 per cent excess.	3550° F.
1 lb. carbon with 17.40 lb. air.....	50 per cent excess.	3326° F.
1 lb. carbon with 18.56 lb. air.....	60 per cent excess.	3129° F.
1 lb. carbon with 19.72 lb. air.....	70 per cent excess.	2954° F.
1 lb. carbon with 20.88 lb. air.....	80 per cent excess.	2797° F.
1 lb. carbon with 22.04 lb. air.....	90 per cent excess.	2656° F.
1 lb. carbon with 23.20 lb. air.....	100 per cent excess.	2520° F.

In practice the furnace tender speedily becomes educated to the point of judging whether a fire is hot enough by its color and by the length of the flame. The more perfect the conditions the shorter and whiter the flame will be.

The pulverized coal introduces very effectively the element of time into the equation. Given a pound of fuel with say 15,000 heat units, these may all be developed by slow combustion at low temperature, or by burning the fuel in pulverized form, quick combustion gives high temperature. The same quantity of heat developed in both cases, but in one instance in a minute and in the other half an hour.

The influence of preheated air upon the economy of the burning of any fuel resolves itself into ascertaining the quantity of fuel which would be necessary to bring the air to the preheated temperature plus the heating of the excess air also to that temperature. Except as a means of transporting heat excess air has no effect in furnace as far as the fuel combustion is affected. This preheating to be of any economical value must be obtained from heat which would else be wasted. To heat all the primary air necessary to combustion and 50 per cent excess air to a temperature of 1000 degrees in excess of the surrounding temperatures would show a saving of some 4100 heat units or nearly 30 per cent of the fuel value. But few of the industries, however, outside of the metallurgical arts permit the waste heat to pass off at such temperatures and volume as to be available. The regenerative checker-work of open-hearth steel furnaces is the best example of success in this preheating.

In this case it has been a necessity to boost the temperature in this way, because the gases from gas producers burned cold, would not give the temperatures necessary for the work to be done.

We may say that four heat units per degree would represent the saving achieved per pound of fuel fired with 50 per cent excess air by heating all the air admitted to the furnace. The measure of efficiency is dependent upon the loss finally carried away in the rejected gases. In the case of regenerative

furnaces this may be lower than in furnaces not equipped with regenerative checker-work, but if to the percentage of loss with regeneratives be added the losses in the gas producers, the pulverized coal directly fired will afford the greater economy of operation.

With the means at hand of obtaining quickly and safely heat of greater intensity than by the use of coal upon grates or in producers, it would appear to render practicable further steps in many of the arts hitherto restricted by the limitations of furnaces at command.

The fear of explosion of coal need not enter into consideration. Coal lying in a bin or conveyor does not explode. It is only when mixed with air or supported by air currents that coal will "puff." In burning it, therefore, we do not mix the coal and air until just as it enters the furnace at high velocity. Against this column of inrushing air and coal the puff cannot take place.

The air is introduced before the coal is turned on, and the coal is shut off before the air. Only by introducing coal faster than it can burn will an explosion occur and then the effect is trifling. It is the gas produced and not the coal that causes this. It wants oxygen and comes outside to get it.

The presence of impurities in the fuel has not much effect. Of course, only combustibles will burn; the incombustibles are inert and do not affect the operation of the furnace. Their effect is in the lessened results from a dollar's worth of fuel negated by a goodly percentage of waste substance. The writer has burned effectively fuel in which analysis showed 52 per cent of ash. Let us reiterate the conditions—*Dry coal, fine grinding, hot chamber or fire box, proper air supply.*

An important part of the subject must not be overlooked. The durability of the furnace is, of course, vitally essential. In the metallurgical arts when extreme heat is an essential part of the operation, care must be taken to avoid destroying the furnace by its own operation. This is not difficult. Much of the troubles have come from the gases impinging upon the furnace walls at points where change of direction of gas travel is necessary, and from too high velocity of gases due to contracted ports.

If the utilized heat is largely absorbed from the gases by the charge, the waste gases will be proportionately less active in scouring the brickwork. In almost any construction except perhaps a rotary kiln it is found necessary to change the direction of the gases in their progress toward the flue. This change of direction causes the gases to impinge upon the diverting bricks with an energy proportional to their velocity. The brick at these points can be fully protected by a system of water-cooled pipes embedded in the walls. The brick may frit somewhat until the area of protection is reached, when further progress is arrested.

The surprisingly small amount of water which it has been found necessary to introduce, maintaining the outlet below 200° F. proves that the cooling effect is limited to a prevention of cumulative action and is not perceptibly a drawback upon efficiency. Of course, the piping must be so arranged that no air or steam pockets shall exist and that the circulation will be proportional to the heat stimulus. One other point and we will conclude. The pulverized coal furnace has no ups and downs. There is no thick fire or thin fire, fresh coal or old coal to insure fluctuations.

The furnace can be always kept at its best working point and so kept it will be heated equally all over. Of course, a large charge of metal to be heated will by its very volume absorb heat rapidly causing a fall in waste gas temperature and possibly a little smoke at first. This is in the nature of things, but the extremely effective conditions quickly bring the charge to a point where the chill is not sufficient to affect combustion and high temperatures come again and smoke disappears. If the work to be done is constant, there is no reason why high conditions may not be uniformly maintained by proper construction and operation.

We believe the subject has been mastered to a point beyond the experimental stage where the full benefits of high efficiency

may be confidently relied upon in this beautiful method of burning coal. As before mentioned, the quality of the coal is not with this method of supreme importance. Indeed, its great value in the developments of the future may lie in the efficiencies obtainable from low-class or refractory fuels hitherto unavailable.

Fuller Engineering Co., Allentown, Pa.

An Investigation of the Air Lift Pump

The air lift method of pumping, though not highly efficient as compared with some other methods, is nevertheless an important one, owing to the many advantages it possesses over other methods in pumping corrosive liquids and raising large quantities of water from wells of small bore. Notwithstanding the fact that this method of pumping has been known for over a century and is now quite extensively used, the amount of reliable data available to the practicing engineer concerning the performance of this type of pump is very meager.

With the purpose of supplying the demand for reliable data, extensive experiments were undertaken in the hydraulic laboratory of the University of Wisconsin under the direction of Messrs. George J. Davis and Carl R. Weidner, assistant professor and instructor, respectively, in hydraulic engineering in the university. The results of the investigation have been published in *Bulletin* No. 450, Engineering Series, Vol. 6, No. 7, University of Wisconsin, which may be obtained by remitting 40 cents to the Secretary of the Regents, Madison, Wis.

The *Bulletin* gives interesting information on the history and development of the air lift pump, showing that the principle was first used by Carl Emanuel Löscher, a German mining engineer, in 1707. The principle of the air lift is discussed and the various theories of its operation are given. The four types of air lift pumps are illustrated and described, namely, the side inlet, the annular air tube, the central air tube and the combination (annular and central air tube).

Among the disadvantages of the air lift pump are cited its low hydraulic efficiency, 25 per cent to 33 per cent; the great depth of submergence required; its limited efficiency in horizontal pumping, and the aeration, which in some circumstances is a disadvantage, causing rusting of the eduction pipe and the deposition of salts in foot-piece.

The principal advantages lie in its large capacity, low maintenance cost, low operating cost, immunity from effects of high temperatures in the liquid pumped, and its reliability.

The investigations at Wisconsin are described in detail, and the results of other experiments are also given. The variables which affect a particular size and type of pump are the following: (1) percentage of submergence; (2) lift; (3) discharge; (4) volume of air; (5) pressure of air. The conclusions which may be justifiably deduced from the Wisconsin experiments are given below, and hold only for the particular size, type and length of pump on which the experiments were performed. The inference, however, may be drawn that these conclusions would hold for other types and sizes.

(1) The central air tube pump has the greatest theoretical capacity for a given size of well.

(2) The coefficient of pipe friction and slip decreases as the discharge increases, and decreases as the ratio of volume of air to volume of water increases.

(3) The coefficient of pipe friction and slip varies with the length of the pump, but seems to be independent of the percentage of submergence and of the lift.

(4) The length of pump, the percentage of submergence, and therefore the lift, remaining constant, there is a definite quantity of air causing the maximum discharge. This quantity of air for maximum discharge, as also the ratio of volume of air to volume of water, differs for different percentages of submergence and lift, the length of pump remaining constant.

(5) The length of pump remaining constant, the maximum output, e.g., foot-gallons, occurs at about the same percentage of submergence for all rates of air consumption, being from 61 per cent to 65 per cent for the pump used in the Wisconsin

experiments. At other submergences the output varies as the ordinates of a parabola having a vertical axis. Under these conditions the lift does not remain constant as the percentage of submergence varies.

(6) The length of pump and percentage of submergence remaining constant, and therefore constant lift, the efficiency increases as the input decreases, that is, the higher efficiencies are obtained at the lowest rates of pumping.

(7) By varying the percentage of submergence, and therefore the lift, the length of pump remaining constant, the maximum efficiency is obtained at approximately 63 per cent submergence for all rates of input or discharge.

(8) The lift remaining constant, the efficiency increases as the percentage of submergence increases, for all rates of input and all practical percentages of submergence.

(9) With the same size and type of pump, the percentage of submergence remaining constant, the efficiency increased as the lift increased for the small lifts experimented on, that is, up to about 24 ft. From a theoretical study, however, the indications are that a point will be reached from which the efficiency will decrease as the lift increases.

(10) Other conditions remaining constant, there is no advantage to be gained by introducing compressed air above the surface of the water in the well.

(11) The type of the foot-piece has very little effect on the efficiency of the pump, so long as the air is introduced in an efficient manner and the full cross-sectional area of the eduction pipe is realized for the passage of liquid. Anything in the shape of a nozzle for increasing the kinetic energy of the air is detrimental.

(12) A diverging outlet which will conserve the kinetic energy of the velocity head increases the efficiency.

A Test of an Edison Primary Battery (Edison-Lalande Cell)

By Dudley Sanford

A precision to within 1 per cent is sought in this experiment.

The battery tested was a new Edison primary battery, type "RR," charged according to the directions inclosed with the cell. All battery connections were soldered to avoid contact resistances.

The test was made by the well-known condenser method. This method involves the determinations of the p. d. across the terminals of the cell when it is on open circuit and when it is closed through a fixed resistance. To obtain these a condenser is charged to the unknown potential and is immediately discharged through a ballistic galvanometer, whose constant has been previously determined by charging the condenser to the potential of a standard cell and allowing it to discharge through the galvanometer. $d = kCE$, where d is the deflection using the standard cell, C the capacity of the condenser, E the e.m.f. of the cell, and k is a constant. Using another cell, $d' = kCE'$. Consequently

$$\frac{E}{kC} = \frac{d'}{d}$$

The apparatus consisted of a 15-microfarad condenser, an external resistance of 0.126 ohm (from terminal to terminal of the cell), a D'Arsonval galvanometer with telescope and scale, and a charge and discharge key (K in diagram).

The procedure followed was this:

At time 0 min. open circuit reading taken with key K' open.
At time 1 min. closed circuit reading taken with key K' closed.
At time 2 min. open circuit reading taken with key K' open.
At time 3 min. closed circuit reading taken with key K' closed.
etc., to end of 60 min. K was then opened permanently, and readings were taken at intervals of 2 minutes. The internal resistance $x = R(F - E')/F'$, and the current $I = F'/R$, where F represents open-circuit voltages, E' closed-circuit voltages, R the external resistance in ohms, and I the current in amperes. The curves showing these quantities are given.

There are several interesting facts to be noted from these curves. The cell has an abnormally high initial e.m.f., 1.03 volts, which drops very rapidly for a short time and is then practically constant at 0.7 volt, though decreasing slightly. The p. d. at the terminals, however, increases gradually at first, but at the end of 60 minutes is nearly constant at 0.55 volt. The current is seen to rise rapidly at first and even at the end of the test is still rising, though not so rapidly. This is ex-

FIG. 1.—ARRANGEMENT OF TEST

plained upon observing the internal resistance curve, for this resistance falls as the cell is used and is at all times low, being but 0.037 ohm at the end of the test. The cell recovers its normal voltage in a comparatively short time.

After running the above test the battery was placed in series with an ammeter and a copper voltmeter and allowed to run until completely exhausted. A voltmeter with a key in circuit was placed across the battery terminals. Readings were taken on the two instruments at suitable intervals of time, which ranged from two hours to thirty hours. The voltmeter readings were correct for the IR drop due to the internal resist-

zinc consumed was 472 g., or 1.2 g. per amp-hour, or 0.000333 g. per coulomb. The accepted value for the electrochemical equivalent of zinc is 0.0003387 g. per coulomb, a difference of only 1.4 per cent.

But, in general, the value of the cell will depend not only upon the quantity of electricity which it will give, but also upon the work it is capable of doing. To know the capacity of a cell only in amp-hours gives inadequate information on which to determine its value to the user. But multiplying the volts by the amperes and integrating over the time of the test gives the watt-hours, a very important factor to be known. This particular cell gave 181 watt-hours of work. Some of this is always lost internally, and the efficiency of a cell varies with the constants of the circuit of which it is a part. But taking the makers' rate of maximum continuous output, 6 amp. and the voltage of 0.7 as given by the test, we find that the efficiency would be 79 per cent. The useful work obtainable would then have been 143 watt-hours. This, however, is the lowest efficiency for continuous output.

From the weighings of the zinc we find that 3.3 g. were consumed per watt-hour, or 3300 g. per kw-hour. The manufacturers' list price for the zinc plates is \$0.00091 per gram. Consequently the cost of producing energy at the lowest efficiency is \$3 per kw-hour. At 100 per cent efficiency it would be \$2.37 per kw-hour. This is on the assumption that the zinc is the only substance consumed in the production of available energy and that the other materials will be recovered. If, however, the user will throw away the remaining materials and buy a complete renewal the cost will be \$11.90 and \$9.40 per kw-hour at the two efficiencies. If in either case the materials are bought in large quantities this cost may be much reduced—50 per cent in lots of \$2,000 or more and proportionately for intermediate quantities. We thus note that under favorable conditions electrical energy obtained from this highly efficient type of primary battery costs around fifty times the ordinary market price of electrical energy.

If the total energy of the cell externally available at its lower efficiency were applied to raising a kilogram weight it would raise it 52,500 meters, or a ton weight a distance of 192 ft. At its full efficiency it would raise a kilogram weight 66,400 meters or a ton weight 240.3 ft.—a total energy of nearly 250 ton-feet. The total weight of the cell was about 20 lb.

The manufacturers of this cell now have a cell (BSCO No. 401) which they claim, on the basis of their tests, is even more efficient than this, yielding 247 watt-hours, or 1.36 times the energy of the type "RR" cell, but its cost for a complete renewal is 1.24 times that of the "RR" cell. Consequently from the cost standpoint it is 10 per cent more efficient than the "RR" cell. The action of the cell, however, is practically the same as is shown in the curves of the first part of this experiment.

NOTE:—The above test was made under my immediate observation and I believe the results are reliable.—EDWIN F. NORTHRUP.

Palmer Physical Laboratory,
Princeton, N. J.

The Data of Geochemistry is the title of Bulletin No. 491, issued by the U. S. Geological Survey, which will be sent free on application. It comprises a manual of geologic chemistry, including chapters on the nature distribution and relative abundance of the

chemical elements, the composition of the atmosphere and of volcanic gases and sublimates, the mineral content of surface and underground waters, the nature of saline residues, the molten magma of the earth's interior, the rock-forming minerals, the composition of igneous, sedimentary and metamorphic rocks, rock metamorphism and decomposition, metallic ores, natural hydrocarbons, coal, lignite and peat. The Bulletin is exceedingly interesting from more than one viewpoint.

FIG. 2.—TESTS OF EDISON-LALANDE CELL.

ance of the cell. From these readings and the proper weighings these results were obtained:

According to the readings of the instruments the total amp-hours (excluding first test) was 389.3. By weighing it was found that 466.05 g. of copper had been deposited, and this corresponds to 392.88 amp-hours. This would show that the readings were correct to 0.0 of 1 per cent. An accuracy to 1 per cent is therefore assumed in the other data obtained. The

Minerals Separation Flotation Plant at Kyle
Copper Mines, N. L.*

By H. Hardy Smith

The ore treatment is almost pure copper pyrites (chalcopyrite) in a gangue of quartz and quartz-felsite. Very little free iron sulphide (pyrite) occurs, and at the time of the erection of the flotation plant the stopes in the oxidized zone had been almost entirely depleted.

This zone only extends to a shallow depth, and, below the 100-ft. level, the sulphide for the most part is clean and

sorted by boys, both pitl ore and waste being picked out. The conveyor discharges into the mill storage bin, of capacity sufficient to keep the mill going for 24 hours.

The crusher, belt conveyor, and pickers only work day-shift

From the mill storage bin the ore is fed by a push feeder to a bucket elevator, discharging on to a shaking screen (48-in. holes, standard spacing). The oversize goes to 30-in. Cornish rolls, and the product from the rolls is elevated by a bucket elevator back to the screen. The undersize from the screen goes to a classifier; spigot to four-compartment May jig.

When the tables were in use the product from No. 1 hutch ran to concentrate bin; Nos. 2 and 3 hutch spigots to a No. 5 Wilfley table; concentrate to bin; tailing to No. 5 Krupp ball mill; No. 4 hutch spigot direct to ball mill; jig tailing to classifier; spigot to waste as jig tailing, overflow to ball mill.

The ball mill crushed through steel screens with clever 3/64-in. round holes to the linear inch.

From ball mill the pulp ran to a three-compartment classifier: first compartment spigot to No. 5 Wilfley; second to another No. 5 Wilfley; third to a Card table; overflow to a baffle board slime thickener; thickened slime to a True vanner, concentrate to bin; tailing to waste. The concentrates from the two Wilfleys and the Card table ran to bin; the middlings to another No. 5 Wilfley, and the tailings to waste. The concentrate from the last Wilfley ran to bin; the middling was returned over the same table, and the tailing ran to waste. Reference to the flow sheet (Fig. 1) will make the scheme clear.

With this arrangement the average extraction was about 74 per cent of the total copper in the feed to the mill. The tailings varied from 1.5 per cent to 1.8 per cent copper, the loss chiefly occurring in the fine and slime. The concentrates varied from 20 per cent to 21 per cent copper.

First Trial of Flotation

Considering the type of plant, these results were very satisfactory, but the advantages of concentration by flotation having

FIG. 1.—ORIGINAL CONCENTRATION PRACTICE.

bright; but in the crushed and brecciated parts of the ore channel, where surface water has circulated freely, the gangue is decomposed and kaolinized, and the copper sulphide badly tarnished.

This class of ore gave considerable trouble at the mill, but, fortunately, was very limited in quantity. A sample of rich ore assayed copper, 21.2 per cent; iron, 24.3 per cent; silica, 28.9 per cent; sulphur, 25.1 per cent.

Original Concentration Practice

The concentration in the original mill was effected by hand-picking, jigging, and tabling. A considerable portion of the copper mineral arrives at the surface in the form of large lumps of very pure quality, eminently suitable for sorting out by hand.

The rich ore is tipped over a grizzly at the shaft bins; the over-sized hand-picked, and the undersize bagged direct.

The medium and poor grades are tipped directly into the bin and trucked thence to the mill. The trucks discharge into a hopper, from which the ore is hand-fed through a chute to a shaking screen (1½-in. round holes) on which it is hand-sorted. The oversize goes to a 15-in. x 9-in. jaw crusher of the Blake type, and is reduced to 1-in. ring size. The undersize from the screen and the crushed ore fall into a bin, and is fed by push feeders to an 18-in. belt conveyor, on which it is hand-

FIG. 2.—CHANGED CONCENTRATION PRACTICE WITH FLOTATION

been brought under the notice of the management, tests were carried out on samples of the milling ore by the Minerals Separation, Ltd., in Melbourne. The results were such that it was decided to replace the tables with a Minerals Separation unit.

The mill building was extended to house the new plant, which, in the original design, consisted of a baffle board slime thickener, two grinding pans, and a flotation machine. The departure from the old flow sheet commenced at the jig.

No. 1 spigot ran to concentrate bin as before; Nos. 2 and 3 to Wiltley table, and table concentrates to bin as before, but tailings to grinding pans. No. 4 spigot product of jig, and

*Excerpt from the *Proceedings*, Australasian Institute of Mining Engineers, No. 7, September, 1912.

classifier spigot product at foot of jig were sent to the pans, and thence direct to flotation machine. Overflow from classifiers at head and foot of jig was sent first to slime thickener and thence to flotation machine. The scheme is shown in flow sheet, Fig. 2.

The grinding pans were 8 ft. in diameter, running at 30 r.p.m., of the classifying discharge type.

Description of Flotation Machine

The flotation machine is of the standard Minerals Separation type, and is classed as a 12-in. unit. For the purpose of making

charged from the bottom of No. 6 hutch through valve *O* which is controlled by suitable means so that the overflow from the lips of the six hatches can be adjusted to what is required.

The stirrers *C* are either driven from a countershaft by quarterturn belts or else by bevel gears, the latter being positive in their action, but objectionable on account of noise and excessive wear and tear.

If required, a middling can be made and returned to the bottom of No. 1 agitating box through pipe *P*.

First Results Unsatisfactory, Necessitating Alterations

When put into operation the results from this plant were not quite satisfactory, and two members of the Minerals Separation staff were sent to investigate. Many minor faults were disclosed, which did not permit proper regulation and adjustment of the machine. The plant was closed, the machine overhauled and radically altered.

The slicing valves, operated by a lever to close or open the mouths of the pipes leading from the bottom of the hatches to the agitating boxes, were replaced by simple flap valves operated through a $\frac{1}{2}$ -in. rod by a thread and hand wheel.

The slicing valve for regulating the discharge of tailings from the machine, originally operated direct by hand, was also altered so as to be controlled by hand wheel and thread.

FIG. 3.—FLOTATION MACHINE

its operation clear to those unacquainted with it, the accompanying sketches (Fig. 3) are submitted.

The pulp with requisite amount of oil added, runs to machine by launder *A*, and discharges into No. 1 agitating box *B*, where it is violently agitated by stirrer *C*, revolving at about 450 r.p.m., with an upward throw.

The aerated pulp escapes through a slot *D* (section), and is deflected downwards into hutch *E*. Bubbles with sulphides attached rise against baffle *F* and form a dense froth on the surface of the hutch, which gradually moves forward and overflows at lip *G* into launder *H*. Any gangue particles attached fall out and pass downwards through space *J* to mix with the remaining pulp and pass out through orifice *K* into pipe *L*, leading to the bottom of No. 2 agitating box *M*.

The overflow from lip *G* is controlled by regulating the size of orifice *K* by means of a suitable valve. At the bottom of each hutch is a hole *N* blocked by a wooden plug or suitable valve, for sluicing out the contents of the hutch when closing down. At the elbows of pipes *L*, are similar holes and plugs for the same purpose.

In No. 2 agitating box *M* the operation is repeated, and so on throughout the six boxes and hatches. The residue is dis-

FIG. 4.—CROWDING BOARDS

This arrangement permitted very delicate adjustment of the overflow from the hatches, which was impossible under the old conditions.

The width of all six hatches being the same, the froth became very thin and poor on the last four. For the purpose of contracting the surface and giving greater thickness and body to the froth, "crowding boards" were put in, which gradually decreased the width of the hutch surface from 11½ in. on No. 1 to 4½ in. on No. 5. See Fig. 4.

With the idea of giving the sulphides less chance of dropping out of the froth, No. 6 hutch was shortened by replacing the baffle with a watertight bulkhead and leading the froth to the front of the machine in a launder. By this means the chance of mineral being lost in the tailings was considerably lessened as the settling space was halved.

The surface widths of the hutches were now as follows:

No. 1	11½ in.
No. 2	11 in.
No. 3	7½ in.
No. 4	5½ in.
No. 5	4½ in.
No. 6	4 in.

A sample of the overflow from each hutch gave the following results:

No. 1		No. 2		No. 3		No. 4		No. 5		No. 6	
Cu. %	Insol. %	Cu. %	Insol. %	Cu. %	Insol. %	Cu. %	Insol. %	Cu. %	Insol. %	Cu. %	Insol. %
27.2	18.9	24.1	27.8	22.3	28.0	15.6	39.8	14.3	45.0	9.4	61.4

This test showed that the grade of concentrates from the last three hutches was not high enough to permit of them being sent to the concentrate bin, so arrangements were made for returning a middling to the machine.

The overflow from the last three hutches was fanned back by a bulkhead at the discharge end of the concentrates launder in front of the machine, and returned to No. 1 agitating box by a 1-in. pipe.

The concentrates from the first three hutches were carried by a tin tray over the bulkhead into another launder running to the concentrate bin.

To get at the insides of the agitating boxes the machine practically had to be dismantled. To obviate this, a rectangular hole was cut in the back of each box, so as to leave about 1½ in. of timber on each side, for the purpose of bolting on a door. The insides of the boxes were now readily accessible, and alterations could be carried out.

Examination showed that the 1½ in. redwood had worn badly, although the machine had only been in operation a few weeks. Liners were made from ¼-in. steel plate and bolted to sides and bottom in order to protect the woodwork from wear.

The orifice in the bottom of each box was at the same time made bell-mouthed, as it was found that by this means the suction caused by the stirrer could be largely increased.

After these alterations had been completed the plant was restarted, with the following results:

Run	Feed % Cu.	Concs. % Cu.	Tails. % Cu.	Extraction %
1	5.1	20.1	2.0	67.5
2	4.4	24.2	2.3	52.7
3	4.0	19.1	1.25	73.8
4	4.7	19.0	2.2	60.1
5	4.0	23.6	1.5	66.7
6	4.1	23.5	2.25	49.8

Formula for Calculating Results

The figures given refer to the machine considered as an isolated unit, and the extractions are the theoretical extractions worked out from the assay values of the feed, concentrate and tailing according to a method which was as follows:

Let x = weight in tons of concentrate when 100 tons of feed is treated.

" a = percentage of copper in feed by assay.

" b = percentage of copper in concentrate by assay.

" c = percentage of copper in tailing by assay.

Then

$(100 - x)$ tons = weight of tailing produced.

Now wt. of Cu. in feed = weight of Cu. in conc. + wt. of Cu. in tailing.

Therefore a ton of Cu. = $\frac{bx}{100}$ tons Cu. + $\frac{c(100 - x)}{100}$ tons Cu.

Putting this as an algebraic equation and solving, we get:

$$\frac{bx}{100} + \frac{c(100 - x)}{100} = a$$

$$x = 100(a - c)/(b - c) \text{ tons.}$$

Hence wt. of Cu. in concentrate = $b(a - c)/(b - c)$ tons.

Hence percentage recovery = $100b(a - c)/[a(b - c)]$.

By substituting the assay values for the symbols in this formula, the percentage recovery can be worked out very readily without knowing any actual weights. It was found exceedingly useful throughout the investigations into the working of the plant, and was used not only for estimating extractions, but also in the solving of other problems, such as the most economical grade of concentrate to produce.

A grading analysis was carried out to discover where the losses occurred. The results were as follows:

Mesh	FEED		CONCENTRATE		TAILING		Extraction %
	Weight %	Copper %	Weight %	Copper %	Weight %	Copper %	
+ 20	1.52	2.2	0.18	12.5	1.85	2.8	11.3
+ 40	13.27	1.2	0.3	17.0	17.53	1.2	4.4
+ 60	15.20	0.8	0.31	18.5	20.77	0.7	11.7
+ 80	3.55	1.15	0.52	24.7	6.10	0.6	38.9
+ 100	22.5	1.4	7.42	23.6	21.4	0.6	28.6
+ 130	3.62	3.8	1.55	21.2	4.2	0.5	21.4
- 130	40.4	5.45	89.7	23.75	28.0	1.2	77.9

Close Sizing Required

These figures showed the necessity for finer grinding and closer positive sizing of the feed to the machine. The presence of coarse particles is even more injurious to the result than the figures show, as the coarse sulphides, in falling through the froth, detach some of the finer material which would otherwise float off. For the purpose of finding out what work the grinding pans were doing, a grading analysis was made, with the following results:

Mesh	No. 1 PAN FEED		No. 1 PAN DISCHARGE		No. 2 PAN FEED		No. 2 PAN DISCHARGE	
	% Wt.	% Cu.	% Wt.	% Cu.	% Wt.	% Cu.	% Wt.	% Cu.
+ 16	16.4	2.3	...	...	10.0	1.4	...	...
+ 30	33.9	1.6	10.0	1.7	19.7	1.0	0.3	...
+ 40	13.0	1.3	17.1	1.2	10.5	1.2	11.0	1.4
+ 60	18.3	1.2	31.9	1.4	18.0	1.3	30.9	2.0
+ 100	6.9	2.1	16.9	1.2	17.0	3.0	23.4	4.1
- 130	11.5	3.7	24.1	5.0	24.8	6.7	34.4	6.2

Depth of discharge:—No. 1 pan, 21 in. above top of dies.

No. 2 pan, 22 in. above top of dies.

With the idea of reducing the +40 product, the lips of the pans were slightly raised and a sizing test made, which showed that the quantity of slime (—130) produced was largely increased, while the +40 product was only slightly reduced.

In spite of improvements in the flotation machine, difficulty was experienced in regulating the overflow from the hutches, and consequently the quality of the work done depended largely on the skill and agility of the man in charge.

The trouble appeared to be due to two causes:

(1) Fluctuation in the quantity of feed coming to the machine.

(2) Fluctuation in the speed of the stirrers.

The latter were driven from the main mill engine, the speed of which altered slightly according to the load on the pans and other units.

The froth on the hutches continued to be thin, with little body and holding power. This was probably due to three causes:

(1) The aforementioned fluctuations in the overflow

(2) Excessive amount of oversize in the feed.

(3) Excessive dilution of pulp in the machine

A test showed the latter to be to 1, and owing to the arrangement of the mill no water could be cut out of the circuit.

A theory subsequently exploded was advanced that the poor froth was due to insufficient sulphide mineral in the pulp, and

the return of the overflow from the fourth, fifth and sixth hutches was expected to rectify the trouble by keeping a certain amount of mineral in circulation.

Final Rearrangement of Mill

It was finally decided that satisfactory work was impossible under the existing conditions, and the plant would have to be closed down and rearranged. The new plant was to embody the following improvements:

- (1) Alteration of pans from classifying discharge to positive central feed type.
- (2) Positive screening of all feed to machine.
- (3) Thickening feed to machine, at the same time forming a reservoir from which a constant supply could be drawn.
- (4) Independent motive power for stirrers, so that speed could be kept constant.
- (5) Apparatus for regulating and keeping constant the supply of oil to the pulp.

The flotation plant was closed and the tables re-started. Plans and designs were prepared along the above lines, and the alterations carried out, occupying about eight weeks.

In the rearranged plant tabling is done away with altogether.

No. 1 jig hutch spigot runs to concentrate bin, as before. Nos. 2, 3 and 4 spigots to classifier; spigots to pans; overflow to thickening box before machine; jig tailing to classifier; spigot to waste (temporarily); overflow to pans. The feed is equally distributed between the two pans by a distributing box. Discharge goes from pans to a bucket elevator, thence to revolving screens; undersize from screens to thickening box before machine; oversize back to pans. The overflow from classifier at head of jig also ran on to the screens.

The spigot of the thickening box ran to machine; overflow to slime thickener; thick slime to machine; clear water to dam. The oil dropped from a cistern into the launder leading to the machine. Reference to the flow sheet (Fig. 5) will make the scheme clear.

The only entirely new units were the revolving screens and the bucket elevator; the rest was merely a re-arrangement of existing plant.

The elevator was constructed with wooden boot of ample size to prevent excessive wear; 3-ft. pulleys, 22-ft. centers; 12 in. x 8-ply Balata belt, traveling 300 ft. per minute, with 10 in. x 6 in. x $6\frac{1}{4}$ in. buckets spaced 15 in. apart; lip of discharge 6 ft. below center of top pulley, to allow buckets to clear themselves, and each bucket had three $\frac{3}{16}$ -in. holes bored in the bottom to assist in this. After the buckets were smooth this elevator did very good work, and so far has given next to no trouble. The screens are revolving trommels of the improved jig type, driven by worm gearing so as to revolve at 11 r.p.m. They turn in opposite directions, and are fed from a distributing box placed between them, having two discharge lips, designed to spread the pulp evenly over the screens. By slipping a board in, the pulp can be cut out from either screen at will. The worm gears are attached to the shaft by a clutch, so that either screen can be stopped when necessary. This arrangement is very compact and neat. The trommels take 36 sq. ft. of wire screen to cover them, and the screen cloth lasts from ten to twelve weeks, according to the mesh and gauge.

Screen Analysis

The screens used were Greening's L. W. B. (600 mesh, 0.0164 in. diam. of wire, 0.0244 in. aperture) on one trommel, and Greening's A. K. D. screen (900 mesh, 0.0116 in. diam. of wire, 0.00217 in. aperture) on the other.

A grading analysis of the product from the A. K. D. screen was as follows:

Mesh	% Weight	% Cu	Mesh	% Weight	% Cu
+40	0.8	1.2	+100	7.7	2.7
+60	18.2	1.4	+130	2.6	2.8
+80	22.9	2.1	-130	47.8	4.8

The product from the L. W. B. screen gave the following figures:

Mesh	% Weight	% Cu	Mesh	% Weight	% Cu
+40	0.7	0.8	+100	8.5	3.3
+60	29.0	1.2	+130	4.3	3.7
+80	23.7	2.3	-130	31.8	5.3

These figures were considered more satisfactory, so henceforth L. W. B. trommel alone was used.

The alterations to the pans consisted in the removal of the baffles and classifying discharge lips, enlarging the discharge holes, and placing a cylinder round the center of the pan with watertight joint at bottom, to take the central feed.

FIG. 5.—TRIAL ARRANGEMENT OF MILL.

It was noticed that, unless the pulp circulated freely from periphery to center by way of the curved channels between the shoes and dies, the pans did bad work, and the launders and screens soon became overloaded. The discharge was baffled to 7 in. above the tops of the dies in the hope that the head thus created would assist the circulation. This resulted in the pans choking so hopelessly that the engine stopped. The pans were then thoroughly cleaned out, the baffle reduced to 4 in., the shoes put hard down, and more water added to the feed.

This brought about the desired result, and the pans did splendid work, as the following grading analyses show:

Mesh	PAN FEED		PAN DISCHARGE	
	% Weight	% Copper	% Weight	% Copper
+16	27.8	1.1	0.4	1.1
+20	10.2	1.2	1.8	1.0
+40	21.2	1.2	12.0	1.0
+60	21.2	1.3	34.0	1.1
+80	8.5	2.5	25.3	1.6
+100	1.8	4.3	7.4	2.7
+130	0.9	4.8	2.9	3.1
-130	6.4	5.1	16.2	3.8

When the sample was taken all the jig tailings were running to the pans. The mill has a capacity of about 60 tons per 24 hours, so, under these conditions, after allowing for jig concentrates and slime eliminated in classifier, each pan was treating pulp at the rate of 25 tons per 24 hours and consuming about 10 hp. in the operation.

Using these figures in conjunction with the above grading analysis, the relative grinding efficiency, according to Stadler's method, works out at 10.4.

Unfortunately, with the pans running under the above conditions (i.e., shoes hard down) the load on the mill engine was too great, and it had a tendency to slow up, so the shoes had to be eased a little. This had the effect of interfering with the circulation in the pans, and a grading analysis showed the relative efficiency to have dropped to 2.6.

Owing to the lack of power the jig tailings had to be run to waste for about 3 hours out of the 24. This trouble has now been overcome by the installation of a small auxiliary engine.

Consistency of Pulp for Flotation

A pulp going about three of water to one of solids can be run to the flotation machine under the following conditions:

Thickening Box.	Slime Thickness.
Depth of discharge, 2 ft.	5 ft. 8 in.
Size of spigot, $\frac{3}{4}$ in.	$\frac{3}{4}$ in.

If necessary, it can be brought as low as two of water to one of solids by altering the spigots and depths of discharge. The dilution in the flotation machine itself is always higher than that of the pulp fed to it, on account of the large proportion of the water in the middling returned. The oil-feeding apparatus consists of two cisterns, one at the back of and above the other. The top one is fitted with a float valve, the float of which rests on the surface of the oil in the one below, and by this means the depth of oil, and likewise the pressure at the tap is kept constant. The drops from the tap are found to remain remarkably constant, except when dirt or water is allowed to get into the oil.

The engine driving the stirrers is a small 6-in. x 6-in. vertical Tangeye engine, running at 250 r.p.m. and 100 lb. boiler pressure. It runs light, developing about 4 hp., and is governed by an ordinary centrifugal ball governor of Pickering type.

The cast-iron stirrers last from 4 to 5 months, and are screwed to the end of the spindles, the direction of rotation tightening them.

The only alterations to the flotation machine were in connection with the returning of the middling and the removal of the concentrate. The middling return pipe was increased to 2 in. in diameter, and holes were left at the bends to enable the pipe to be cleaned out when choked, by inserting a length of iron wire. This operation was very seldom necessary.

Another launder was added to the front of the machine, the inside one carrying the middling and the outside one the concentrate. Removable tin trays carry the concentrate across to the outside launder, and when necessary the tray is removed and the overflow from any hatch is allowed to return with the middling. With the old arrangement enough fall could not be given to the tray carrying the concentrate, and in consequence it had continually to be cleared with a scraper.

When put into operation the new plant soon justified the alterations. Once regulated, the overflow from the hutchers remained steady and constant for an indefinite period, provided nothing went wrong with the rest of the mill.

On several occasions the flotation machine ran for a couple of days without any attention other than oiling. When all the jig tailings were being treated the concentrate from No. 4 hatch was so rich that it was run direct to the concentrate bin, and by adjusting the machine the grade of No. 5 could be raised sufficiently to do the same with it. This left the overflow from No. 6 hatch alone to be returned as a middling.

Strange to say this alteration had no apparent effect on the grade of the bulk concentrate produced, and certainly no deleterious effect on the efficiency of the machine.

The re-agent used is *Eucalyptus* dries oil, distilled in the bush country at no great distance from the mine. It is fed to the launder leading to the machine at the rate of 12 cubic centimeters per minute, which works out at a little under $\frac{1}{2}$ -lb. per ton ore. It costs 8d. (\$0.16) per lb. delivered at the mine.

No acid at all is used, one attempt to do so proving disastrous.

Effect of Oxidized Ore

A certain class of ore frequently gave trouble at the machine, and when present in the feed invariably decreased the extraction. This type of ore was that mentioned at the beginning of these notes—i.e., decomposed, oxidized, and kaolimised lode matter.

On one occasion, when the pulp was discolored from a whitish-grey to a dirty yellow by this material, the process became inoperative, no true froth forming whatsoever, and the pulp leaving the machine at practically the same value at which it came in. Large slimy bubbles and small masses of coagulated sulphides covered the hutchers.

The bubble films were very tenacious, the bubbles clinging to the sides of the hutchers and allowing the turbid water to flow away from beneath them.

No improvement took place while the pulp showed any signs of discoloration. Salts in solution, or acidity of the pulp and excessive fine slime were considered likely causes of the trouble. The above extreme conditions were never again encountered, but on several occasions trouble was experienced with an excessive quantity of froth, made up of large bubbles with slimy, cohesive films.

A sample of pulp taken while these conditions ruled gave the following results:

- (1) The decanted solution contained 36 grains to the gallon of salts in solution.
- (2) The decanted solution was neutral to litmus.
- (3) 52 per cent of the solids in the pulp passed 130-mesh sieve.
- (4) The -130 product assayed 0.11 per cent of oxidized iron

The +130 product assayed 0.03 per cent of oxidized iron

The bulk sample assayed 0.07 per cent of oxidized iron.

(NOTE.—The oxidized iron was taken as a measure of the oxidized material.)

After this each daily sample of feed was assayed for oxidized iron, but no definite relation could be detected between the amount of oxidized iron present and the result of the day's run; but amounts above 0.05 per cent seemed to have bad effects, and when above 0.07 per cent the results were invariably poor.

The deleterious effect of the oxidized and decomposed material seemed to be to its physical rather than its chemical properties, and the peculiar nature and excessive quantity of the slime formed from it appeared to be responsible.

Favorable Percentage of Slime

Daily grading analyses of the feed, extending over a lengthy period, showed that more than 40 per cent of slime was undesirable, the best results being obtained with from 25 per cent to 35 per cent.

Sometimes the presence of even undecomposed felspar in the gangue appeared to be responsible for a dirty, slimy froth.

At Kyloe the ideal ore seems to be a clean sulphide mineral in a clean quartz gangue. Given a feed approaching this ideal, the flotation machine is capable of marvelous work, as the following figures will show:

Feed % Cu	Concentrate % Cu	Tailing % Cu	Extraction %	Ratio of Concentration
3.8	25.1	0.95	77.0	6 to 1
3.0	23.5	0.85	74.3	5 to 1
3.0	24.2	0.65	81.0	8 to 1
3.15	23.7	0.55	84.5	7 to 1
4.1	25.6	1.05	77.5	6 to 1
4.4	24.6	0.9	82.5	5 to 1

These figures represent consecutive daily runs on good clean

ore, the tailing sample being taken automatically. The machine is considered as an isolated unit. It can be safely asserted that no other concentrating apparatus yet devised can show better or even equally good results on feed which contains particles from 40-mesh up to the very finest slime.

After the flotation machine had been running about 5 months the boxes began to leak, and examination showed that the wood work had been worn away behind the liners. The bottoms and sides had to be renewed, and to save similar trouble in future the $\frac{1}{4}$ -in. steel liners were replaced by $\frac{1}{2}$ -in. cast-iron ones, designed with interlocking joints so as to protect the wood-work entirely from wear. These liners can easily be removed and renewed, and have given no trouble.

The concentrates from the machine are run to bins, where they are settled, and the persistent froth beaten down with a water spray. Certain classes of slimy froth give trouble by building up and overflowing the bins. When the concentrates settle the flow is diverted to another bin, and the water syphoned off.

The sloppy mass is then shovelled into barrows and wheeled to the drying floors, which consist of thick cast-iron plates under which hot gases from a furnace flow. Owing to the high percentages of water the concentrates take some considerable time to dry.

Filtering was attempted, but, owing to the slimy nature of the concentrates, was not a success, and the output was not large enough to warrant the installation of some form of pressure filter.

When dry the concentrates are shovelled from the floors into bins, and bagged for despatch to the smelter.

The following figures show the recovery made by the mill each month, calculated from the assay value and weight of feed and the value and weight of concentrate despatched:

Month	Average Value of Tailing % Cu	Extraction %
1st	1.26	82.7
2nd	1.11	86.1
3rd	1.03	85.4
4th	1.0	87.0
5th	0.95	93.0
6th	0.89	90.5
7th	0.81	85.0
8th	0.95	95.0
9th		

The accepted assay value of each lot of concentrate sent to the smelter is given below:

Lot No.	Accepted Assay Value % Cu	Lot No.	Accepted Assay Value % Cu.
1	23.2	7	25.27
2	26.17	8	25.24
3	25.95	9	25.92
4	25.05	10	26.00
5	25.52	11	25.06
6	25.66	12	25.48

General Results Improved by Flotation

These figures show an increase of over 10 per cent in the recovery and a little under 5 per cent in the grade of the concentrate, over the old system of tailing. The importance of the latter may be gauged from the fact that after deducting freight and smelting charges, with copper at £50 (\$250) a ton, a ton of copper in a 20 per cent concentrate is only worth £28.76 (\$144) to the company while a ton of copper in a 25 per cent concentrate is worth £32.52 (\$162)—an increase of £3.76 (\$18) per ton of copper, representing on a 1000-ton output £3,760 (\$18,800) a year. The average cost per ton milled for the twelve months previous to the installation of the flotation plant was 78½ shillings (\$1.90). The average cost since the installation is 8.21 shillings (\$2.00)—an increase of 4.8 pence (£0.10) per ton milled, or about £370 (\$1,850) on the yearly output.

The grade and tonnage of the ore treated was about the same

for 1911 when tables were used, and 1912 when flotation was adopted, thus affording an excellent opportunity for comparing results under the old and new systems of milling.

Copper is taken £60 (\$300) a ton in both cases.

The figures show that, while the expenditure increased £1,300 (\$6,500) the revenue went up over £4,300 (\$21,500), leaving over £3,000 (\$15,000) to the credit of the flotation plant.

The cost of construction and alterations came to about £1,300 (\$6,500) so that the new machinery has paid for itself more than twice over during the first year of operation.

In addition to this, it is only fair to the flotation plant to draw attention to the fact that disbursements and maintenance on the old units have been larger than they were during 1911, owing to depreciation with age.

Nichols-Hesse Dinner

By the joint action of the executive officials of the American Chemical Society, American Electrochemical Society, American Institute of Chemical Engineers, Chemists' Club, the New York Section of the Society of Chemical Industry and the New York Section of the Verein Deutscher Chemiker, it is proposed to give a complimentary dinner to Dr. W. H. Nichols and Dr. B. C. Hesse as a mark of appreciation of their work in connection with the Eighth International Congress just closed. Professor Edward W. Morley, as the honorary president of the Congress, has been asked to preside at this dinner.

It is proposed to hold the dinner on April 19 at the Chemists' Club, the price to be \$3.00 per plate without wine. Rumford Hall will accommodate hardly much more than 250 guests, and the men who intend to go to this dinner should make early reservations.

Milwaukee Meeting of the American Chemical Society

The forty-seventh annual meeting of the American Chemical Society will be held in Milwaukee, Wis., from March 23 to 28. Headquarters will be at the Hotel Pfister. The meetings will be held at Marquette University. A feature of the convention will be an excursion to Madison, Wis.

Atlantic City Meeting of the American Electrochemical Society

The spring meeting of the American Electrochemical Society will be held in Atlantic City, N. J., from April 3 to 5. (Thursday to Saturday of the first week in April). Headquarters will be at the Hotel Traymore.

A meeting of the board of directors will be held on the evening of Wednesday, April 2. The convention will start on Thursday, April 3, with the annual business meeting which will be followed at once by a meeting devoted to the reading and discussion of papers, to be continued in an afternoon session. For the evening it is intended to arrange a smoker.

Practically the whole day of Friday (April 4) will be devoted to an excursion to various chemical plants in and near Philadelphia where the members and guests will be taken by a special train. After their return in the evening to Atlantic City, dinner will be taken and there will be a lecture with demonstrations by Prof. E. B. Kenrick of the University of Toronto.

The Saturday morning meeting will be devoted to the presidential address by Dr. W. Lash Miller which will be in form of an introduction to the symposium of papers on electroplating and electrodeposition of metals, while another professional session in the afternoon, devoted to a continuation of this symposium and to the reading and discussion of other papers, will conclude the meeting.

The fall meeting will be held in Denver, Colo.

Dr. W. Lash Miller, of the University of Toronto, is the president, and Dr. J. W. Richards, of Lehigh University, South Bethlehem, Pa., is the secretary of the American Electrochemical Society.

Symposium of Papers on Alumina

Four papers on the Production and Uses of Alumina, by J. W. Richards, S. A. Tucker, A. H. Cowles, and L. E. Saunders

A symposium of papers on alumina—its production and its uses—was the feature of a joint meeting of the New York Sections of the American Chemical Society, the American Electrochemical Society, and the Society of Chemical Industry, held on February 7, 1913, at the Chemists' Club in New York City.

The meeting was held under the auspices of the New York Section of the American Electrochemical Society and was called to order by the chairman of the section, Mr. Elmer A. Sperry. In a brief business meeting which followed, this section elected officers for the coming year as follows:

Mr. Lawrence Addicks, superintendent of the Chrome, N. J., works of the U. S. Metals Refining Company, was elected chairman, and Mr. H. B. Coho, of the United Lead Company, New York City, was re-elected secretary-treasurer.

Mr. E. A. Sperry then made some introductory remarks on the subject of alumina. He referred to the presence at the meeting of Mr. Bradley and Mr. Cowles, two prominent pioneers of the metallurgy of aluminium and

sketched the effect which cheaper alumina would have on the industry of aluminium and aluminium alloys. He referred especially to the remarkable properties of duralumin for many purposes in the industries. Samples were exhibited.

Then followed two papers by Dr. Jos. W. Richards, of Lehigh University, and by Prof. Sam. A. Tucker, of Columbia University, on the production of alumina and ammonia by the Serpek process which is attracting so much attention at present.

The Serpek Process

By J. W. Richards

The production of aluminium nitride (AlN) on a large scale is proposed in the process of Ottokar Serpek, followed by the decomposition of the same by water or caustic soda solution, thereby liberating the nitrogen as ammonia and producing alkaline aluminate solution from which pure alumina can be obtained. This rather daring chemical proposition has directed attention to aluminium nitride, the conditions of its formation and its properties.

The existence of aluminium nitride was suspected for some time before it was isolated. A rather indefinite number of years ago, probably about 1890, the attention of the writer was

directed by his father to the fact that when metallic aluminium in a melted condition was skimmed, and the skimmings or dross laid to one side, that on pouring water upon them while still warm these skimmings gave off an odor of ammonia. The explanation which was then figured out for this phenomenon was that the hot aluminium in the skimmings oxidized to alumina, and that the rather high temperature thus produced locally caused the aluminium also to unite with the nitrogen of the air and form the nitride. In other words, that some of the aluminium united first with the oxygen and immediately thereafter some also with the nitrogen of the air. On sprinkling

with water the nitride would react according to the following reaction:

In the light of subsequent investigation and the formation of aluminium nitride in other ways, it appears that the explanation given in these early days was correct and that aluminium nitride is formed directly under such conditions from metallic aluminium and the nitrogen of the air.

LeVerrier, later, proved the presence of traces of

nitrogen in commercial aluminium by dissolving it in caustic potash and passing the nitrogen evolved into Nessler solution, obtaining from it the ammonia reaction. He thus proved the presence of nitrogen in the metal and suspected it to occur as aluminium nitride dissolved in the excess of metal. In further experiments he treated aluminium with a current of nitrogen gas until it was saturated, and noted that this produced considerable diminution in the tensile strength, elastic limit and elongation of the metal.

Prof. Mallet later obtained aluminium nitride corresponding closely to the formula AlN by heating metallic aluminium in the carbon crucible to a moderate temperature for several hours in contact with dry sodium carbonate. Some alumina is formed, some sodium vaporizes and some carbon is deposited: the reaction is probably as follows:

Aluminium nitride containing 34 per cent of nitrogen and 66 per cent of aluminium was obtained as little yellow crystals and amorphous drops. When calcined in the air it was found to lose nitrogen and form alumina; it was decomposed in moist air, losing its transparency, becoming lighter yellow, evolving ammonia gas, and finally leaving the alumina residue.

Apparatus for carrying out Serpek process (*b*, supply of ground bauxite and exit of gases; *a*, kiln for calcining; *m*, hopper for supply of calcined bauxite to kiln; *b*, kiln for nitride reaction with electric resistance furnace; *h*, chamber for removal of nitride; *j*, gas producer; *c*, chamber for deposition of silica; *c*¹, *c*², *c*³, *c*⁴, air supply inlets for combustion of gases. From Serpek patent 996,032).

Caustic potash solution and melted caustic potash both attacked it actively, disengaging ammonia and forming potassium aluminate.

A later experimenter described the compound as a grey amorphous powder, but otherwise with properties similar to those described.

Coming now to the work of Serpek we find his first proposition to be the production of aluminium nitride from aluminium carbide, which is indeed a possible reaction. In his U. S. patent 867,615 (filed June 19, 1906, issued October 8, 1907) he describes the passing of nitrogen or a gas containing nitrogen over aluminium carbide as an initial material heated to red heat. He describes the volume of the carbide increasing as it is converted into nitride, and that the absorption of nitrogen was increased by diluting the carbide with such materials as carbon or alumina or aluminium chloride: also that traces of hydrochloric acid or sulphur dioxide in the gas currents facilitated the conversion. The claims of this patent are essentially for the method of producing aluminium nitrides by heating aluminium carbide in an atmosphere containing nitrogen to a red heat with or without the diluting substances admixed and with or without traces of acid gas in the nitrogen used.

Attention may be called to the term "aluminium nitrides" in this patent, corresponding to the fact that in the product thus obtained by Serpek he found that part of the nitrogen in the product was driven off by contact with air, and a further part by boiling with water, and a still further part by treatment with caustic alkali solutions. These facts pointed to the non-homogeneity of the product, which thus appeared to consist of a mixture of different nitrides instead of one distinctive chemical compound.

Continuing his work we find that Serpek later concluded that it might be possible to obtain the nitride directly from mixtures of alumina and carbon, which it will be recalled he used as diluent substances in the conversion of the carbide. He was apparently not able at that time to produce nitride directly from these two substances, but found that in the presence of a small amount of metal such as copper or iron, which is capable of forming an alloy with aluminium the formation of nitride from the mixture took place. In his U. S. patent 888,044 (filed May 24, 1907, issued May 19, 1908), he describes mixing alumina with carbon in the proportions necessary for formation of CO gas (Al_2O_3 3C), adding about 5 per cent of either copper or iron or a mixture of the two, and heating the mixture to a red heat in a current of nitrogen gas, at which temperature the partial formation of an alloy of aluminium produced by reduction, with the copper or iron would be initiated. The idea seems to have been to produce a mixture on the point of reaction from its constituents and then to super-add the influence of the current of nitrogen gas. Traces of HCl or SO_2 gases are said to facilitate this reaction also, and the product is described as almost pure aluminium nitride. The reaction is described as developing a high temperature as soon as it is initiated. The claims are for producing aluminium nitrides by heating the mixture of alumina with carbon and a metal capable of forming an alloy with aluminium, to red heat in an atmosphere containing nitrogen, with or without the presence of small amounts of acid gases.

It is evident that in this method the conversion of alumina into aluminium nitride was aimed at, with the assistance of small amounts of metals as catalytic or assisting agents. Whatever may have been the results of the previously described process it finally led the investigator in the end, to the method described in Serpek U. S. patent 987,408 (filed December 15, 1909, issued March 21, 1911) in which aluminium nitride is produced directly from Al_2O_3 and carbon in the presence of nitrogen, at a much higher temperature than previously recommended. This patent appears to be the result of considerable investigation on the conditions of this direct production and specifies very exactly the temperatures at which the direct conversion takes place. The patentee speaks of the general supposition that extremely high temperatures would be required for such direct conversion, such as the highest temperatures

of the electric furnace, but explains that by careful investigation he had found that if the temperature is closely watched some combination of nitrogen with aluminium can be observed even at 1100 deg. C.; that at 1500 deg. nitrogen is absorbed fairly rapidly, at 1700 deg. energetically, and that at 1800 to 1850 deg. the reaction may be almost designated as violent producing almost chemically pure nitride. Further, Serpek found that temperatures higher than this gave a smaller yield, and that somewhere above 2000 deg. the production practically ceased, the decomposition temperature of the nitride appearing to be about 2120 deg. C. This brilliant piece of experimental work really laid the foundation for the Serpek process as it now exists. The inventor further discovered that impure alumina, such as bauxite ore, was converted at somewhat lower temperatures than the pure material, evidently owing to the catalytic effect of the impurities present.

The claims of this patent are for producing aluminium nitride by heating aluminous compounds and carbon, or more specifically alumina and carbon, in an atmosphere containing nitrogen to temperatures not exceeding 2000 deg. C., and preferably about 1800 deg.

Reference may very properly be made at this point to the experimental investigation and confirmation of these results by Prof. S. A. Tucker and Henry L. Read given before the Eighth International Congress of Applied Chemistry, published in its Transactions and in volume 22 of the Transactions of the American Electrochemical Society. This investigation, carried on in the electrochemical laboratory of Columbia University under carefully regulated conditions showed traces of nitrogen absorbed at temperatures of 1000 to 1100 deg. and as much as 30 per cent of nitrogen in selected portions of the product made between 1800 and 1900 deg. The product made at higher temperatures contained less nitrogen and was either sintered or fused. Impure alumina, such as bauxite, was found to be converted more easily than pure alumina, and the definite statements of the last Serpek patent were confirmed and verified.

Serpek's U. S. patent 996,032 (filed June 21, 1910, issued June 20, 1911), contained a detailed description of the apparatus intended for the commercial manufacture of the nitride from bauxite or other aluminium ores. The plant consists in two superposed rotating cylindrical kilns, similar in construction to a cement clinkering kiln. The kilns are inclined in opposite directions, so that the material being preheated in the upper kiln and passing from right to left for instance, falls into the opening of the lower kiln for treatment at higher temperature where it passes from left to right. Bauxite alone is passed through the upper kiln, and there calcined; then mixed with the necessary carbon in its passage from the upper to the lower kiln and the mixture treated by nitrogen at a high temperature in the lower kiln, which is provided with a detachable electric resistance furnace about midway of this length and which is intended to subject the charge therein to the reacting temperature about 1800 to 1900 deg. C. The material is discharged from the lower end of this kiln into an air-tight receiver. A large gas producer of the ordinary type furnishes producer gas (approximately $\frac{1}{4}$ CO, $\frac{3}{4}$ nitrogen) to the lower end of the lower kiln. This gas entering at a temperature of about 400 deg. becomes highly heated as it passes through the kiln in a direction contrary to the descending charge, and at the electrically heated zone at a temperature of 1800 to 1900 reacts upon the mixture forming nitride. After leaving the high temperature zone the gas enriched in CO coming from the reaction preheats the descending charge, issues from the upper end of the kiln into a vertical closed chamber and passes through it to the opening of the upper kiln where it meets a blast of air which burns it for the purpose of heating the contents of the upper or calcining kiln.

The apparatus as thus described achieves a methodical heating of the reacting mixture, utilizes the CO gas made in the producer and also that evolved by the reaction in the furnace; aims at an intimate mixture of the charge by the rotation of the cylinders and intimate contact of the nitrogen with the charge. The inventor states that the silica impurity of the

charge is mostly volatilized (probably as reduced silicon) from the charge at the reacting temperature and is thus carried out in the gases; and that the apparatus may be used for producing other nitrides made by analogous reactions.

The claims cover an apparatus comprising the features of a revolving inclined upper cylinder discharging into an inclined lower cylinder revolving in the opposite direction, through a vertical chamber in which the gas from the lower cylinder may be burned combined with an electric detachable electric resistance heating furnace within the lower cylinder. One claim is for the single feature of a rotary calcining cylinder carrying a detachable electric resistance furnace.

Undoubtedly a large amount of excellent investigation has been put upon this process, and it certainly deserves commercial success. The method is being tested in France upon a large experimental scale.

The Relation of the Production of Alumina to the Fixation of Nitrogen

By Samuel A. Tucker

The connection of nitrogen fixation and the production of alumina is to be found in the Serpek process and probably in this process only. The Serpek process is primarily one for the fixation of nitrogen, but necessarily involves the production of alumina as a by-product and this by-product is all important to the success of the process commercially.

Briefly the Serpek process takes alumina and carbon in the proportions to form aluminium nitride in a strongly heated atmosphere of nitrogen, or

The range of temperature necessary for this reaction is from 1600 deg. to 2000 deg. C. according to Serpek. The product obtained contains about 30 per cent nitrogen in the form of aluminium nitride, and is thus considerably richer in fixed nitrogen than calcium cyanamide which rarely runs over 20 per cent.

This reaction appeared so important to me that I thought it was worth while to investigate it and in conjunction with Mr. H. L. Read, the process was tried on a small scale. The results¹ of this work have been read at the recent Congress of Applied Chemistry, and it will be unnecessary to repeat them here, excepting that we found that the reaction worked satisfactorily on a small scale, the product contained 30 per cent of nitrogen, and that bauxite was the best material with which to supply the aluminum. The temperature is important. Below 1600 deg. practically no nitrogen is fixed, while above 2000 deg. C. decomposition is likely to occur. I would like to know more as to the influence of temperature, and I had expected to conduct some experiments on this point so that I might give you this information now, but an accident to the electric furnace prevented it.

The commercial product must be nearly pure aluminium nitride, and at first sight seems to consist of two forms, the blue and the yellow. Professor Luquer has examined these specimens microscopically and while his examination has not yet been completed, he tells me that the internal structure is the same, both are strong double refracting and show uniaxial structure. With our present information, it would be difficult to figure the cost of production of this material, and even the power necessary for its manufacture is probably not generally known.

The question of the necessary time to convert the charge is important and in our experiments we found that it had a great influence on the nitrogen content of the product. It, therefore, seems necessary that the mixture should be heated to a high temperature for a considerable time.

This is different from the Frank process for cyanamide in that the temperature for the actual nitrogen fixation is relatively low. Granting that the process can be worked out on a satisfactory cost basis, we see that the production of alumina is an all important consideration. By proper treatment of the

Serpek product there seems to be no difficulty in obtaining the nitrogen as ammonia and the aluminium as alumina, and the latter should be practically pure Al_2O_3 .

It might be supposed that the alumina so produced could be used over again in the process, but aside from its value in connection with the aluminium industry, pure alumina is not advantageous as a raw material, as it requires a higher temperature than bauxite. The process is, therefore, necessarily associated with the production of aluminium. If we might suppose that the Serpek process were to be conducted on the same scale as the Frank process for cyanamide manufacture it is evident that it would involve the production of a large amount of alumina. From figures recently published regarding the Frank process, we find that the capacity output of all the plants covering various parts of the world for 1912 is roughly 200,000 tons of cyanamide. If we figure this as containing 18 per cent. nitrogen, it involves the fixation of 36,000 tons of nitrogen. With the Serpek product at 30 per cent. nitrogen content, it would require the production of 120,000 tons to equal this, and after decomposing to obtain the ammonia as follows:

we obtain 140,200 tons of alumina. This quantity of alumina should give 79,704 tons of metallic aluminium.

In the year 1911 we find that the capacity of all the plants producing aluminium was 62,100 tons, but that the estimated production actually was about 45,000 tons. We thus have raw material for the production of 34,000 tons of alumina in excess of present requirements. Of course, the process will not be conducted on such a scale for some time to come, and by that time there might well be a market for the alumina.

There appears to be no danger from the lack of bauxite, as I find that in this country 155,618 tons were produced in 1911 and 106,000 tons in France for the year 1910.

As the Serpek process would necessarily come into competition with the other means of fixing nitrogen, and particularly with the cyanamide process, it might be well to consider for a moment a few points in connection with the latter.

Briefly the Frank-Caro process for making cyanamide is to subject finely ground calcium carbide to the action of pure nitrogen at a temperature of from 1000 to 1200 deg. C. The energy necessary at this absorption stage is probably very small, as heat is evolved by the reaction:

and the expenditure of energy is chiefly in the manufacture of the calcium carbide. Various conditions have to be observed in this absorption part of the process. The nitrogen must be practically free of oxygen and the temperature must not rise to the dissociation point of the cyanamide, which is probably about 1370 deg. C. The product so obtained contains anywhere from 15 to 22 per cent of nitrogen. The nitrogen is obtained by passing air over copper to take up the oxygen, or by fractionally distilling liquid air. Both systems seem to be in use, but with the latter some treatment of the resulting nitrogen with copper would probably have to be employed as nitrogen obtained from liquid air contains upwards of 8 per cent oxygen.

The process seems fairly complicated, but possesses the advantage over the high-tension arc systems of fixation in that a better return of nitrogen is obtained for the power used. In the Frank process the chief expenditure for power is in the formation of calcium carbide. The average of several plants making carbide is 5.2 kilograms of 80 per cent carbide per kilowatt-day of 24 hours. This gives 4.16 kilograms of pure calcium carbide, which corresponds to 173 grams per kilowatt-hour. Now if this is converted to cyanamide having a 20 per cent nitrogen content, we get 43.2 grams N per kilowatt-hour.

The Birkeland-Eyde process obtains about 57.1 grams nitric acid per kilowatt-hour and the nitrogen content is 12.7 grams. We thus have about three and one-half times the nitrogen fixed by the Frank process as cyanamide as we do for the Birkeland-Eyde process as nitric acid, and this is probably the reason for its being established on such a large scale.

¹See this Journal, volume X, p. 745 (1912).

As to the relative value of the fixed nitrogen fertilizers, we have no very precise information. Taking the various products adapted to this purpose in the different processes, we get calcium nitrate by the Birkeland-Eyde, calcium cyanamide by the Frank, and lastly ammonia by the Serpek process. These must all be compared with Chili sodium nitrate and the general opinion seems to be that the latter is the most valuable.

Field experiments have been conducted with cyanamide and calcium nitrate, but precise information is lacking. It would seem, however, from what has so far been done that we should put them in the following order: Chili saltpeter, calcium nitrate, cyanamide, ammonia.

The action of cyanamide is quite different from the others; it supplies a large amount of calcium which may or may not be an advantage. Its slow solubility is, however, advantageous.

Ammonia in the form of sulphate is pretty well understood in its relation to fertilization and for that reason the Serpek product should have a ready market in this connection.

* * *

The two papers by Professor Richards and Professor Tucker were discussed together. Some of the points touched upon in the discussion were the possibility of an intermediate reaction preceding the formation of the aluminium nitride, and the way how the impurities, especially silica, are removed in the process. Attention was called to the fact that French bauxite is in the average low in silicon and high in iron and American bauxite high in silica and low in iron, and that this might have some effect on the operation of the process with American bauxite.

After the conclusion of this discussion, in which some ten speakers participated, Mr. Alfred H. Cowles, of Sewaren, N. J., presented his paper on his own new alumina process, the fundamental points of which were already described by him in his paper before the International Congress of Applied Chemistry in September, 1912 (our Vol. X, page 659). Mr. Cowles' present paper contained, however, much that was new. We give it herewith practically in full:

Cheaper Alumina and Aluminium from Mineral Silicates

Through Reactions with Alkali Chlorides, Lime and Steam, and Between Florida Phosphate Rock, Potash Feldspars and Acids with the Production of Cheap Hydrochloric Acid, Potash Salts, Phosphate Fertilizers and the Production of Material for the Manufacture of Glass or Hydraulic Cement

By Alfred H. Cowles

Let two briquets be formed, one of kaolin or clay containing 19 parts of anhydrous pure clay and 23.4 parts of salt, and the other briquet containing the same relative proportion of salt and dry kaolin as the first, and fifteen parts of charcoal per one hundred parts of the mixture be present in the second briquet. If now these two briquets, each of the same size and form, be kept heated to a temperature equal to or just above the vaporizing temperature of salt, and if vapor of water in an oxidizing atmosphere surrounds them, it will be found that each briquet begins to be converted over its surface into a sodic-silico-aluminate which would have the formula of $(\text{Na}_2\text{O})_2(\text{SiO}_2)_2\text{Al}_2\text{O}_3$ if the clay and salt be pure. The vibrating gaseous molecules of watery vapor and oxygen bring about this change over all exposed surfaces of the two briquets. This difference in the conversion will, however, be found. The briquet containing no charcoal will require nine times as much time for the conversion to penetrate to its center between walls, as the briquet containing charcoal.

This result is not self-apparent as the reaction requires an oxidizing atmosphere to oxidize the sodium produced before it volatilizes out of the briquet. That this result would occur, was based upon hypothetical reasoning on my part and its demonstration as a truth was brought about by experiments per-

formed in the laboratory of The Electric Smelting & Aluminum Company at Lockport, New York. By coincidence Dr. Adolf Kayser was my assistant in performing the experiments.

Dr. Kayser in the early '90's, attempted to develop this reaction commercially using briquets containing no charcoal in large kilns of a down-draft nature. The work had proven a failure as had also the work of William Gossage in 1862, and that of Gruneberg and Vorster about 1874-76. During these experiments Dr. Kayser was of the opinion that they could not succeed because, as he thought, it would produce reducing conditions. The experiments, however, proved that the conversion penetrated the briquets nine times faster with charcoal in them, than was the case when briquets contained no charcoal. This result taught that it was necessary to expose large surfaces or porous masses to bring about a rapid conversion. This could be effected in more than one way, but the problem of cooling the gases and simplifying the elimination of dust led to the adoption of a tunnel furnace of the Gröndal type, with modifications to render it suitable for the process.

The fact that the reaction could be made to proceed rapidly opened up an entirely new vista, one of assured success to the process. It meant that the column of fuel gases and nitrogen necessary to pass through the charged furnace would become so far reduced as to permit of efficient commercial condensation of the hydrochloric acid evolved. It meant the employment of cheap fuel, sawdust or charcoal made from sawdust with possible by-products from the same, and far greater capacity of output with the same cost of plant. It meant that the process could be applied to other aluminous materials, such as potash feldspar mixed with chloride of potash or salt, and securing the chemically equivalent reaction.

Dr. Kayser had evolved a method of opening or rendering leachable alkali-silico-aluminate containing sufficient alkali, which means nearly one molecule more than that which occurs in feldspar. This he did by heating to a sintering temperature two molecular weights of lime to each molecular weight of silica in said compound, after which, the product may be leached and the alkali aluminate very effectively removed therefrom. Our company acquired this patent from him.

The process is easily understood. In the manner in which we are attempting to perfect it at Sewaren, N. J., in our present work, briquets are formed by the same clay-working machinery that produces what is known as hollow-ware or conduit bricks. When the clay, salt, and sawdust are mixed together and water is added, this mixture acts almost the same as clay as to plasticity in passing through the briquetting machinery, but unlike the clay brick, it does not shrink or expand from the period of its first formation during drying and until it is formed into a finished product containing soda, silica, and alumina.

These briquets are loaded onto flat cars, the surface of each car as now used being 12 ft. long and 5½ ft. wide, holding fifty-five bricks. (See Fig. 3, p. 661 of Vol. X of this journal.) These loaded cars are passed first through a drying furnace where the free water is driven off, and then by a transfer track, into a vestibule connected with the long kiln. (See Fig. 4, p. 661, Vol. X.) By a hydraulic pusher, after the door of the furnace is opened, and the door of the vestibule is closed, the loaded car is gradually pushed into the charging end of the furnace, and a train of fourteen cars in front of it are also gradually pushed forward towards the discharging end of the furnace, while a finished carload is coming out at that end.

The cars are covered with firebrick, the latter of a nature to protect them from being materially attacked by salt vapors. A sand seal extends the whole length of the furnace, and pure air, by a blower, is blown under the train of cars in such a manner as to prevent any leakage of hydrochloric acid fumes downward. In operation, the temperature of all exposed iron parts of the furnace are kept above the boiling point of mixed acid and water, and as is well known, at this temperature vapor of hydrochloric acid does not attack iron.

Knowing the composition of the clay and the percentage of salt in the briquets steam is blown into the discharge end of

the furnace, and the rate by pounds weight of steam per minute is read by an indicating steam-flow meter. Suppose this rate is adjusted to the rate of feed of the material on the cars to effect the decomposition of salt with the formation of, say, 33 per cent hydrochloric acid in water. In this case there is required in the chemical reaction only about one part of water to thirteen parts to produce the 33 per cent acid, hence it will be noted that the quantity of steam blown in to form such acid is thirteen times greater than that which takes place in the reaction. The amount of steam, if the heated zone in the furnace be long enough, can be so reduced as to still permit much water being admitted to the coke towers to complete the condensation of all the acid.

Above, and on the end of the furnace where the cars are pushed in, is a large exhaust fan which draws all the gases from the furnace and forces them onward through a condensing system where the hydrochloric acid is condensed. The furnace is 184 ft. long, or ignoring the vestibule is 170 ft. long. Beyond the zone of high temperature towards the fan there is a distance of 79 ft. where the briquet-loaded cars act as a scrubber to remove any sublimed salt and other dust from the gases at the same time that the incoming briquets are being heated by the hot gases passing over them.

In addition to this we are constructing a dust-settling and cooling chamber in the iron pipe line between the furnace and the acid condensing system.

The reaction that takes place in the furnace will vary according to the composition of the aluminous material and the amount of alkali chloride mixed therewith, but typically it may be written as follows:

The gaseous products in the above are carried into the condensing system after cooling. The briquets maintain their original form, and before the cars issue from the discharge end of the furnace they are cooled down by the inflow of the measured quantity of steam and air that is sucked in. This steam and air become preheated by the hot bricks before it reaches the combustion zone of the furnace, and the finished bricks are cool enough for men to handle them with gloves as they discharge from the furnace.

In our work at Sewaren we have discovered that our acid condensing apparatus with air cooling has only about one-third the capacity that it should have. It is at the present time being enlarged, and tourells submerged in water being added to it into which about 18 Beaumé acid will be run against the flow of the gases before the latter reach small coke towers. The escape of acid fumes has been so great that we have only been able to make four experimental runs of about thirty hours' duration each with the large furnace, but the results secured have taught us the necessary changes to be made in the acid condensation system and the necessary changes to get a full conversion in the furnace. The whole product of the last two runs has been analyzed, but not of the first two. The furnace was operated with only one set of oil burners and a car of briquets fed into the furnace during every forty minutes.

Before starting to build our plant at Sewaren briquets had been made containing as high as 33 per cent of sodic oxide and were white and free from iron.

We found by the analysis that the Sewaren briquets were but little more than half converted, hence it was rather against my desire to read this paper at this time. The briquets still contain a large amount of salt. The furnace is provided with another set of oil burners to meet this contingency, but we have not yet used them.

After completing the enlargement of our acid condensing system we contemplate using both sets of oil burners and adding a trifle more sawdust to the bricks, in which case there is no doubt but that we will produce the same results as in our laboratory work, with one exception. In the laboratory work the furnace was a deep, circular furnace filled with briquets and an oil flame and vapor of water were passed downward through the briquets. Under these conditions the iron as an

impurity in the clay was carried downward as chloride of iron and small portions of it passed off with the acid and other portions condensed in the bottom of the furnace and in the iron pipes through which were drawn the gaseous product from the furnace from under a grate at its bottom.

As the bricks were secured white, it was concluded that we would secure the same result in our large work, but this conclusion, as given in a paper read before the Eighth International Congress of Applied Chemistry (this journal, Vol. X, p. 659, October, 1912) has, by practice, proven erroneous. As the surfaces of the cars are cooler than the briquets, we find a portion of the iron as either ferric or magnetic oxide on the car surfaces and a part still remaining mainly on the surface of the lower portions of the briquets. Thus it is the iron oxide remains on the cars and briquets and does not pass out with the gases to vitiate a part of the acid. The acid produced thus far only shows the presence of sulphuric acid by the most delicate test. It is free from arsenic and has but traces of free chlorine, iron chloride, sulphuric acid and ammonium chloride, and with our final settling dust chamber completed, it will be practically free from salt and aluminium chloride.

LIME OPENING PROCESS

In order to secure from the sodic-silico-aluminate material of the briquets the sodic aluminate contained therein we intend to put down a kiln of the rotary type to sinter this material, which is easily friable, after mixing with it lime in such proportions as to form di-calcium-silicate from the silica in their composition. This compound is insoluble, while the sodium aluminate is soluble. The material as thus treated is not fused, but sintered in such condition as to form an easily leachable mass. The reaction involved in this process is as follows:

Limestone, calcite or marl in their chemical equivalents may be used instead of anhydrous lime.

The product thus secured will be leached by ordinary methods.

In the foregoing reaction any amount over two molecular weights of calcium oxide to each molecular weight of silica leads to the formation of insoluble calcic aluminate, and less than two molecular weights is not sufficient and leaves undecomposed a portion of the insoluble sodic-silico-aluminate. Under either of these contingencies, marked loss in the recovery of alumina may occur. Experimentally up to 90 per cent of the sodic aluminate has been leached from the above clinker, while there was left behind a mass of di-calcium silicate.

PRODUCTION OF HYDRAULIC CEMENT

According to Newbury's formula hydraulic cement is tri-calcium-silicate with up to 8 per cent of aluminium and iron oxides in a mixed condition being permissible in the formula. The above-mentioned di-calcium-silicate product is hydrated. If it now be ground and then heated with one added molecular weight of lime it forms a product that is in composition the same as that of hydraulic cement, but unless the material used is very pure, experience at Sewaren discloses that it will give a light gray cement and not a white, as the writer believed when he read a paper before the Eighth International Congress of Applied Chemistry.

Inadvertently there was printed in the paper read at that time the following statement:

"When briquets are made containing 32 per cent of sodic oxide the output of 30 per cent hydrochloric acid should be about 1½ tons of acid to 1 ton of salt and clay in the charge"

The statement should have read: To 1 ton of salt in the charge, about 1.75 tons of 33 per cent acid.

USE OF DI-CALCIUM-SILICATE AS A MATERIAL FOR GLASS MAKING.

If in the foregoing lime sintering process should there intentionally be left in the insoluble di-calcium-silicate after leaching 15 or 20 per cent of its alumina and alkali contents, there remains a product that is excellent for the manufacture of window and bottle glasses. Its use would call for the addition of silica and more alkali to its composition. Glass can stand a considerable percentage of ferric oxide and alumina in its manufacture.

OXALIC ACID

Nearly all the ingredients needed to produce oxalic acid, excepting sawdust, come from the products of these processes. The carbonic oxide from the acid towers can be scrubbed to free it from the last traces of hydrochloric acid and then passed over or through sawdust mixed with caustic alkali heated to the proper temperature producing an oxalate of the alkali, which treated with calcium chloride gives calcium oxalate and with sulphuric acid gives oxalic acid with calcium sulphate precipitated, frees the oxalic acid. This acid is most largely manufactured in Europe, but has a great consumption in America in our laundries.

USE OF HYDROCHLORIC ACID IN PRODUCING PHOSPHATE FERTILIZERS

The question may well be asked what use can be made of the large amount of hydrochloric acid that this process will produce should it supply as much alumina as will be needed for the production of the world's future supply of the metal aluminium. The author has pending a number of United States and foreign patents which may place hydrochloric acid in competition with sulphuric acid as now used in the manufacture of soluble forms of calcium phosphate mixed with calcium sulphate so largely used as a fertilizer. A pure calcium phosphate rock is anhydrous tri-calcium-phosphate. With it there is almost always associated considerable calcium carbonate, silica, alumina, and other impurities.

If this rock be ground to an even degree of fineness and then thoroughly digested with weak hydrochloric acid, the quantity of acid employed being theoretically just sufficient to dissolve all the free calcium carbonate, ferric oxide and one molecular weight of calcium oxide contained in the tri-calcium phosphate, the insoluble residue that is left is di-calcium phosphate. The soluble products, calcium, magnesium, and iron chloride, will exist in solution. By filtering and passing water through this mass, the soluble chlorides formed can easily be removed and either run into the sea or submitted to other possible uses.

The insoluble di-calcium-phosphate remains in a non-hydroscopic pulverent condition that can readily be applied to the soil by present methods of distribution. This is the product that all soluble phosphates revert to when they are applied to the soil as fertilizers. It has, however, one advantage over the soluble phosphates produced with sulphuric acid, namely, it is not loaded down with a large burden of calcium phosphate upon which transportation charges must be paid. If calcium sulphate is desired for fertilizer use it can more cheaply be produced from native gypsum rock. If the digestion is not thorough some soluble phosphates pass into the rich solution of chlorides. These phosphates can be precipitated by the use of a proper amount of calcium carbonate.

In Idaho, Utah, Montana, and Wyoming the United States Geological Survey have in recent years discovered and examined the largest deposits of phosphate-bearing rock ever known to the world. In this general region these rocks that have now been withdrawn from location covered an area as of Sept. 1, 1912, of nearly 2,212,000 acres.

The process as thus far described ends in securing the alumina as a sodic aluminate solution which can be completely purified from silica, titanitic acid, and the iron oxide by a very simple means of precipitation. The final precipitation of the alumina in its purest form is brought about by Dr. K. H. Bayer's process, patented about 1894. It involves a very peculiar and interesting phenomenon. When previously precipitated alumina is added to the sodic aluminate solution even without shaking; if one observes a beaker containing this solution and the precipitate he will note the precipitate to begin to grow almost like a mushroom and in a few days' time nearly all of the alumina precipitates itself leaving a liquid containing nothing but caustic soda and a comparatively small amount of alumina. By an added step, which on account of patent matters I ought not to discuss, the last traces of alumina from the solution may be recovered and the solution left as strong solution of caustic soda needing slight concentration to prepare it for the market.

This general process opens the way to secure alumina

cheaply or as a by-product in conjunction with these other products of great consumption in the industrial world. There is required 1.9 lb. of alumina to produce 1 lb. of aluminium, there being no appreciable loss in the present method of manufacture of the metal over the theoretical amount. This weight of alumina costs from $6\frac{1}{2}$ to $7\frac{1}{2}$ cents according to the latest data I have regarding the same and is the heaviest cost in producing the aluminium. By a general introduction of this process we may hope to see the cost of production of aluminium reduced 4 or 5 cents per pound, and when it comes to a general electrification of our world's railroads and a greater use of electric transmission lines and trolley wires, we will find aluminium a much more serious competitor of copper than at present, and eventually it will almost entirely supplant copper except in motors and generators.

POTASH ALUM FROM POTASH FELDSPAR AND ROCK PHOSPHATE

We all know the great need of potash salts as plant food and the scarcity of their supply, also the abundance of potash feldspar rocks containing great quantities of potash and the abundance of rock phosphate. Several years ago I was experimenting with the mineral wavelite, which is a hydrated phosphate of aluminium. Knowing that calcium sulphate or burned gypsum was slightly soluble in water, and that aluminium sulphate was very soluble in water, I reasoned that if proper proportions of aluminium phosphate and calcium phosphate were ground together and a minute amount of sulphuric acid were added to start the reaction, that the two bases should trade their acids if enough acid were present to form an insoluble form of calcium phosphate.

On trying the experiment, I found this reversal occurred and that aluminium sulphate could abundantly be leached away from the mixture. Further, knowing that di-calcium silicate was quite an insoluble body and if sulphuric acid were added to it the calcium sulphate formed would be but slightly soluble, it occurred to me that were I to take potash feldspar, for instance, orthoclase, whose formula may be written $K_2O \cdot Al_2O_3 \cdot 6SiO_2$, and grind it with just sufficient rock phosphate so that there would be present in the mixture two molecular weights of lime to each molecular weight of silica in the feldspar, or other potash silicates, such as leucite, and that if I added just the right proportion of sulphuric acid to this mixture I would have a chemical system which under conditions of solubility would degenerate to the form of insoluble di-calcium silicate and soluble aluminium sulphate, potash sulphate and ortho-phosphoric acid, H_3PO_4 .

Upon having heated together the above mixture to merely a sintering temperature of about 1000 deg. C., and leaching with sulphuric acid, my first experiments gave almost 100 per cent.

For the purpose of this lecture I have had the work repeated. In figuring the amount of sulphuric acid to use, my assistant has taken a little less acid than was used in the former work and the result of the leaching has given a product containing all the potash and all the alumina from the feldspar, but only part of the phosphoric acid. Duplicate results have been secured substituting hydrochloric acid for sulphuric acid. The liquor in these two cases will give us either potash alum or a double chloride of aluminium and potassium associated with all the phosphoric acid contained in the rock phosphate employed. By this process the di-calcium-silicate or a slightly lower form of calcium silicate would be available for use in either the manufacture of cement or the manufacture of glass. Feldspar can be secured very free from iron, so also can rock phosphate. The iron, however, follows the other products into solution. From either potash, alum or the double chloride of aluminium and potassium the chances of securing pure alumina are very favorable. Upon heating to a dull red heat, aluminium sulphate breaks down into alumina with liberations of sulphuric acid (SO_3) and the potassium sulphate can then be leached away. In the case of a double chloride of aluminium and potassium at a very low heat in the presence of vapor of water, hydrochloric acid is given off with the formation of alumina, the chloride of potassium remaining as such, which can be leached away from the alumina.

To secure pure alumina from the above solution of chloride or sulphate salts with phosphoric acid is promising. The potash alum, however, cannot be separated by crystallization. By precipitation with sodic or potassic aluminate, if too much of either of these salts be not used, pure phosphate of aluminium may be secured. This audience will appreciate other possibilities.

POTASH PHOSPHATE FERTILIZER

In the foregoing I have described the sintering at a comparatively low temperature of rock phosphate and potash silicates. I wish to call attention to the fact that this mixture in

LOCKPORT PLANT OF ELECTRIC SMELTING AND ALUMINIUM COMPANY

some cases, and sinter in this instance with a proper amount of sulphuric acid added to it, or hydrochloric acid, if the hydroscopic properties be not detrimental in the latter case, is of greater fertilizer value than rock phosphate when used alone. By this new process the silica has taken place of much acid that would be required, and the product is not loaded down with calcium sulphate, but, instead, is loaded with potassium sulphate and the lime and silica is in such form as to be sufficiently soluble to furnish silica to plant food, and, further, the soluble lime is in a condition to act on potash minerals in the soil, displacing potash therefrom, thus rendering more potash available for plant food.

The soap industry is founded on the use of alkalis, and I have pointed out to you the possibilities of the fertilizer industry, the glass industry, and the cement industry as all being possible future contributors to the cheap production of aluminium. For the production of cheaper aluminium must come with the expansion of electricity to furnish power for the electrification of our railroads and other industrial uses.

Mr. Cowles then showed in the form of lantern slides the views of his Seward plant, which were given in our Vol. X, p. 650 (October, 1912), and also a view of his Lockport plant, which is herewith reproduced.

Mr. Cowles' paper was discussed at some length by various speakers.

The last paper on the program related to new uses of alumina, the author being Mr. L. F. Saunders, of the Norton Company, of Niagara Falls, N. Y.

Uses of Alumina as an Abrasive and Refractory

By L. E. Saunders

Most people undoubtedly consider aluminium metal manufacture as the only significant factor in the consumption of bauxite and other aluminous ores, and the refined product alumina.

I am therefore going to call attention to another industry which places dependence on aluminous ores, the abrasive business. Unless something calamitous happens to all of us during the next few months, this year will see a consumption

of aluminous ores in the world corresponding to some 10,000 tons of aluminium metal in the manufacture of grinding wheels. It may not be realized to what extent abrasives enter in the equipment of the modern machine shop. Hardly an essential in our daily walks of life but is dependent in this new machine tool for its manufacture. The breakfast food with which we start the day, the stove on which it is prepared, the morning paper which gives it flavor, the street car, railroad train or motor car which takes us to business, the marble panels in our palatial offices, the typewriters which write our letters, the pearl buttons on our gloves, the leather gloves themselves, nearly all our activities, and finally, the polished granite columns at our graves would not be here in their present perfection were it not for the artificial abrasive which either makes an integral part or a machine to accomplish the end in view.

Broadly speaking, grinding is done in two classes, first, metals of high tensile strength, such as steel of all classes, malleable iron, etc., and, second, metals of low tensile strength, such as cast iron, brass, aluminium, etc. As about 75 per cent of the world's pig iron is converted into steel, and finished and wearing parts are largely made of this material, it may be seen that the first class covers the wider field. Aluminous artificial abrasives are used almost exclusively for this purpose and this fact offers a reason for the figures given above. The change from natural to artificial aluminous abrasives is world-wide, the use of emery and corundum showing a steady decrease. The reason for this lies in the lack of uniformity and grinding efficiency of the natural minerals and the possibility of exact duplication of quality in the electric furnace product. It is also possible to give such products varying characteristics for various uses, the accomplishment of which depends on the skill of the manufacturer and knowledge of the laws governing its properties. Such materials are therefore in use varying from an alumina content of 70 per cent to one of over 99 per cent.

As an adjunct to and an offshoot of this industry the aluminous refractory is coming into its own. (This journal, Vol. IX, p. 257, 1911.) While these articles are of little account as consumers of alumina, they are of considerable interest and value to the laboratory worker. The demands are increasing steadily as the users become better acquainted with the properties. One of the problems we have to contend with is to persuade the chemist that we have not attempted to furnish a sovereign remedy for all laboratory ills. The products may be varied in their properties, and an advantage in one direction is usually accomplished by the sacrifice of some other quality. Numerous published criticisms have appeared, most of which would have been quite uncalled for if the problems had been submitted first to the manufacturer so that a selection of the proper grade could have been made—neither in the abrasive or refractory field is alundum a panacea. When we are told the job, it is not very often that we fail.

In closing, let me say that new processes for purifying aluminous materials are still of great interest to us. A chance of securing cheaper raw materials looks good to us and from the user's standpoint we wish each experimenter success in his own work.

Industrial fellowships are established at the Universities of Kansas and Pittsburgh, under the direction of Dr. Robert K. Duncan, for the purpose of promoting the increase of scientific knowledge in chemical industries. The scheme involves financial assistance from any industrial concern with a problem to investigate, the co-operation of the university and the personal work of one or more fellows. The results, if any, are shared by the company, the university and the fellow. According to a recent announcement by Dr. Duncan before the Franklin Institute, the scheme is working well and has developed no weaknesses during the five years of its trial. Eleven fellowships have been completed at the University of Kansas and nine are still in force. At the University of Pittsburgh there are sixteen in force. The subjects of investigation have a wide range in industrial chemistry and metallurgy.

Titanium as Used in Steel Making

By E. F. Lake

During the last decade a great deal of progress has been made in the iron and steel industry and its products greatly improved by the perfection of new methods and the discovery and adoption of different elements for use as purifying or alloying material. One of the last elements in this category, but by no means the least, is titanium, which was first reduced to a fused condition by Moissan in his electric furnace. Although he separated it from all other elements he could not get it quite free from carbon. Between that time and the present, much experimental work has been done on metallic titanium but only very recently has it been made to better the various metal products when used in their manufacture. It was not until 1907 that the first heat of titanium steel was teemed and rolled in America and yet more tons of it are now made than of all the other alloy steels put together.

Metallic titanium is hard and brittle and has a dark grey color with a decided metallic luster; it being not unlike silicon and also resembling iron in appearance. It melts at about 2300 deg. C., and its atomic weight is 48.1. In nature it is never found native. It either occurs as titanium dioxide, (TiO_2), in the three distinct crystallized varieties of rutile, brookite, and anatase; in combination with iron, as titaniferous iron, containing ferrous titanate, (FeTiO_3), which is of the most interest to steel makers and sometimes contains 40 per cent of titanium, and in a number of iron ores and minerals. It is found in combination with the protoxide of iron, mixed with more or less of the peroxide of the same metal. It has been found in many minerals and rocks, as well as in clays and soils resulting from their decomposition. Thus it appears to be very widely distributed in the earth's crust but no one locality holds any large quantity. It has also been detected in meteorites and in the sun.

Titanium belongs to the same chemical group as silicon, zirconium, cerium, and thorium, but it occupies a position nearly midway between tin and silicon and by some might be grouped with the former element. In other ways it is allied to iron, chromium, and aluminium. It is attacked by common mineral acids and has a great affinity for both oxygen and nitrogen. Titanium burns more energetically in oxygen than any known substance and when heated in it creates an instantaneous dazzling flame like lightning. Its combination with nitrogen gas is attended with the evolution of heat. Moissan's investigations led him to the conclusion that it was the only undisputed example of the combustion of an element in nitrogen; while Wöhler stated that no other element burns in nitrogen with so much energy as titanium. No other facts have since been brought to light to disprove these statements.

The titaniferous iron ores are very abundant throughout the world and in some parts exist in very large deposits. In fact whole mountains of it are located in the United States and Canada, and in Sweden and Norway. These were considered worthless for many years as the titanic acid produced a very infusible slag and attacked the lining of the blast furnace. It was even considered dangerous to the operations of the furnace to have too much of this ore present. In many cases the titanium combined with the nitrogen, set free by combustion, in the high heat of the blast furnace and formed a compound that entered the slag and made it so heavy it completely choked the furnace. Violent boiling has been caused in experiments carried on in the electric furnace and in some cases the charge has risen completely out of the furnace.

Most of this is due to improper fluxing, as the best of results were obtained in a blast furnace in the Adirondack Mountains in New York State, U. S. A., where iron ores very high in titanium were smelted for a period of something like twenty years. In England, at Norton-on-Tyne, the same thing has been done for several years. At the present time many tons of high-grade pig iron are being made from such ores in several different countries. They are generally so low in phosphorus and sulphur that ways and means are continually

being found to use more and more of these ores. Many blast furnaces, that do not use titaniferous ores entirely, are mixing them with other ores for this reason. Another use to which they can be put is, as an addition to the bath in basic open-hearth furnaces. Here they would act as a desulphurizer and flux for the basic slag in place of fluor-spar as they perform exactly the same service as this latter material.

The greatest benefit that has accrued to the steel maker's art from titanium is not in the ways and means that have been devised for using the titaniferous ores, but from using the titanium in the ferro form, as a purifying and alloying material.

No method was found for reducing the ore and extracting the pure titanium until the electric furnace, with its high temperatures, was made a practical success. This was due to its comparatively high melting point of 2300 deg. C. Titanium also has a specific gravity of 5.174, which is considerably lower than that of iron at 7.2. This, in combination with the high point of fusion, made it impossible to combine metallic titanium with the molten bath of iron or steel, when held at workable temperatures, and hence no beneficial results could be obtained until ferro-titanium was produced and experimented with.

The nature and action of the metal was such that it encouraged investigation and experimentation. Through these it was found that raising the titanium content of the ferro alloy multiplied the difficulty encountered when trying to induce it to combine with molten iron or steel, and made impossible the task of getting it to enter into solution. On the other hand it was necessary to get enough titanium into the bath to perform the intended mission. The many tests made conclusively proved that the best results were obtained from ferro-titanium that contained from 10 to 15 per cent of titanic acid. When 20 per cent was present it would not dissolve thoroughly at the usual working temperature of an iron or steel bath, and higher percentages caused a segregation that produced hard spots in the metal. The 10 to 15 per cent ferro-titanium generally contains about 6 per cent of carbon and 5 per cent of all other impurities. As one-half of 1 per cent of titanium is all that is usually added to the molten steel, the percentage of carbon and other impurities, in the finished product, can easily be controlled.

The great affinity of titanium for both oxygen and nitrogen makes it of special interest to the steel maker and also to the steel user. It has been proven, beyond a doubt, that these two latter elements lower the static strengths and dynamic properties of steel, the wearing qualities and resistance to friction, and increase its tendency to corrode. That they are more injurious to steel than sulphur and phosphorus and present in larger quantities than has hitherto been supposed, is also considered a fact by those that have made the most careful investigations along this line. That a sulphur content as high as 0.13 did not develop "hot-shortness" in steel, and had no other injurious effects, was fully demonstrated by one series of tests in which the other impurities in the metal were reduced to traces only.

Removing the gases from steels, by the addition of titanium, directly increases the cohesive force in the mass by removing the microscopic, or even larger, bubbles which they form. These destroy the cohesive force between the molecules surrounding such spaces. Indirectly it strengthens the metal by preventing these gases from forming injurious compounds with other elements that are present.

As both oxygen and nitrogen are gaseous by nature it is difficult to analyze steels for these elements, but satisfactory results are now being obtained. In one lot of twenty-four specimens the oxygen content was found to range from 0.021 to 0.046 per cent. These may seem small enough to be ignored, but it is the combinations the oxygen will form, and not alone the percentage of this element, that must be considered when its effect on the steel is judged. As an example of this, we talk about the injurious effects of 0.05 per cent of sulphur, when it is really the 0.13 per cent of manganese sulphide that alters the quality of steel. Oxygen has

only one-half of the atomic weight of sulphur and, owing to its being capable of forming many more compounds, it exerts a much greater influence. Thus 0.05 per cent of oxygen may mean that 0.22 per cent of ferrous oxide is present and this is a large enough percentage to have an important influence on the metal. The oxygen was determined by heating very fine drillings of steel in a current of pure dry hydrogen, and weighing the water, formed by the reduction of the oxide.

When oxygen comes in contact with steel, either in a moist or heated atmosphere, oxides are formed. These show as tiny black specks under the microscope, when the surface is highly specular and magnified at least 1000 diameters. These oxides are always found in steels that develop blisters when being pickled. Bessemer steels contain the largest amount, with open-hearth steels second; crucible steels next, and electric furnace steels the most free from oxides. In fact steels have been made in the electric furnace that are apparently entirely free from oxides. The blisters are probably formed by the reduction of the oxides by the nascent hydrogen evolved during the pickling operation. When pickling high carbon steel rods they sometimes fracture in the bath and the same force that forms blisters on the softer steels might cause the harder steels to rupture. When titanium is added, in the proper manner, to the bath of molten steel it forms, with the oxygen, a titanium-oxide. This, being lighter than steel, floats to the top of the bath; enters the slag and is removed therewith. Thus no injurious compounds are formed with the oxygen.

That the reduction of the oxides is brought about by the nascent hydrogen may be easily demonstrated. To do this a polished surface should be made the negative electrode in a solution that is just strong enough to make it an electrolyte. The solution may be composed of 0.002 per cent, or two parts of a neutral salt, or an alkali, in 100,000 parts of distilled water. This should be heated to boiling and an electric current passed through it, to evolve the hydrogen in contact with the polished surface. After exposing the specimen for a few minutes it should be withdrawn and dipped in alcohol to prevent oxidation before it is examined.

Such a specimen will show that the manganese sulphide is unaltered, and the oxide is removed. The pits left by this removal of oxide will be larger than the specks of oxide formerly seen, as any oxide that may be in solution around these specks will also be removed. This explains why more oxide is found on chemical analysis than can be seen under the microscope. That both the current and the hydrogen are necessary can be proven by the fact that no pitting is produced by the same process minus the electric current.

That oxygen increases the tendency of steels to corrode is shown by the fact that polished specimens, containing oxides, begin to rust much sooner than those that are practically free from them. In dilute acid solutions this is greatly accelerated. That all impurities except oxide are electro-negative, as compared with iron, is generally accepted as the reason for the more rapid corrosion. Oxide of iron being electropositive when compared to iron, the electromotive force causes a dissolution of the steel in the vicinity of the oxide. This action continues until the oxide is removed by other means as, of itself, it does not dissolve with the surrounding steel. Welds are never perfect as we are not able to squeeze all of the oxide out of the joint. It there forms into small globules that interrupt the cohesive force which binds the molecules together.

These, as well as other, instances of the injurious compounds that are formed in steel by oxygen, show the necessity of removing as much of this element from steel as possible. While silicon, manganese, and other of the more common elements have been used for a long time for this purpose by steel makers, they still leave a percentage in the metal that is large enough to become an important factor. Quite recently, therefore, aluminium, vanadium, titanium, zirconium, etc., have been brought into use to remove the smaller percentage that is left by the ordinary steel making methods, and very good results have been obtained with all of them. Titanium does this work as effectively as any of the foregoing and is destined to be

much more universally used as it is easily made to perform its mission and is much cheaper in cost. In the manufacture of steel rails with the Bessemer process it only adds about \$1.20 per ton to their cost. In higher grades of steel the additional cost is seldom up to \$2.00 per ton.

That nitrogen is injurious to steel is shown by the fact that each increase causes the elongation to rapidly diminish and reduce its ductility. At first a slight increase is caused in the toughness but after that this also rapidly diminishes, together with the loss of ductility and elongation. Generally speaking steels have lost their elasticity, and their elongation and contraction have become nil when a nitrogen content of between 0.030 per cent and 0.035 per cent is in the steel. An 0.5 per cent carbon steel might not lose its ductility, however, until from 0.04 to 0.05 per cent of nitrogen was reached, and in the softer steels from 0.05 to 0.065 per cent might be present.

It might be claimed by some that hydrogen gas caused this brittleness that is assigned to nitrogen, or at least a part of it, as hydrogen imparts extreme hardness to otherwise pure iron. Hydrogen gas, however, is easily driven off by any of the re-heatings the iron or steel gets and doubtless none of it can be found in the finished product.

In open-hearth steels the nitrogen content is usually between 0.020 and 0.025 per cent; in Bessemer steels from 0.018 to 0.062 per cent; and crucible steels from 0.010 to 0.015 per cent. Thus at least 0.012 per cent of nitrogen must generally be reckoned with. Steels made in the resistance electric furnace are practically free from nitrogen and hence are an exception to the above rule. Those, however, that are made in the arc electric furnace, in the presence of basic slags, are liable to contain enough nitrogen to be injurious.

The Manchester Steam Users' Association made some investigations of boiler plates that had failed. They found that the nitrogen content was from 0.0146 to 0.023 per cent and that this was from three to five times as great as the maximum found in any of the good plates that were tested. The notorious boiler plate from the Imperial Russian yacht *Livadia* contained 0.0123 per cent of nitrogen and 0.047 per cent of phosphorus. In the above tests a sample cut from a plate that burst under the hydraulic test showed 0.020 per cent of nitrogen and 0.052 per cent of phosphorus. Here the nitrogen was four times the amount of that found in any good plate tested. From these results the conclusion was drawn that nitrogen was more injurious to steel than phosphorus and that the one was as liable to produce brittleness and "cold shortness" as the other. It was concluded that no investigation was complete that did not determine the percentage of both phosphorus and nitrogen. They also established a rule as follows: The sum of the percentage of phosphorus, plus five times the percentage of nitrogen, should not exceed 0.08 per cent.

Nitrogen will not combine with steel by heating the two together, but in an atmosphere of ammonia they will unite. If the coking of the fuel has not entirely removed the nitrogen in the coal, ammonia is doubtless introduced into the blast furnace in that way. When nitrogen has once entered the pig iron in the blast furnace it cannot be removed by any subsequent reheating and hence is found in the finished steel.

Titanium, however, has a great affinity for nitrogen and when properly added to a steel bath it forms with it stable nitride which is lighter than the molten steel and raises to the slag. This nitride shows as tiny red crystals under the microscope. The very energetic reaction of titanium and nitrogen takes place at a temperature of about 800 deg. C. Combinations that are of no value are formed, however, if the air is carelessly shut off during this reaction and thus the good effects of their union will be greatly lessened, if not completely nullified.

Titanium is about the only element that readily combines with the nitrogen in steel and carries it away to the slag. While both silicon and manganese reduce the oxides they have practically no affinity for nitrogen. Chromium burns in oxygen at 1700 deg. C., but does not combine with nitrogen any more than does silicon or manganese. Molybdenum, even in pow-

dered form, will not form into combinations with nitrogen at temperatures up to 1200 deg. C. Tungsten will not form a nitride with nitrogen. Nickel also has no effect on nitrogen. While vanadium is a great scavenger of oxygen, it only effects the nitrogen in steel to a very limited extent. This leaves titanium alone as the nitrogen scavenger.

The proper method of adding the ferro-titanium to the molten metal is of vital importance. When improperly added it passes into the slag without going through the steel to search out and seize the oxygen and nitrogen and carry them with it to the slag. Some have advocated putting the ferro-titanium into the furnace but this only comes from a misconception of its nature and action, as silicon, manganese or spiegeleisen can better do the rougher work of oxidizing the steel and are much cheaper materials to use. Furthermore, adding the titanium in the furnace might cause it to work off into the slag and allow the gases to re-enter the steel before teeming. Titanium should only be used for removing the last traces of these gases, after the ferro-silicon and manganese have done their work, and hence should be added in the ladle.

The ferro-titanium comes well broken and ready for use. Being lighter than iron, it will not sink and disseminate when added near the top. Therefore, it should be put in, a shovelful at a time, while the molten metal is flowing into the ladle. If the stream is made to strike the ladle at one side a swirling and churning action is given the molten mass in the ladle and any ferro-titanium that might be floating on the surface will be engulfed and disseminated through the mass where it is quickly dissolved and starts on its mission. It should never be preheated as this sometimes prevents a complete reaction in the steel. Some begin by adding 1 per cent of titanium and gradually reducing this until the beneficial results obtained begin to diminish from the maximum point obtained.

The steel in the ladle should never be above the normal temperature for good untreated steel, as the reaction set up by the titanium causes the temperature to rise to a certain extent. After adding the titanium the ladle should be allowed to stand from five to fifteen minutes so the impurities and slag, released by this reaction, will have time to raise to the top of the ladle and not segregate in the steel. It is very difficult to make steel makers realize this as no other material they use acts in this manner. They fear the molten metal will become chilled and hence want to pour it into ingots before the titanium has accomplished its purpose. After standing, however, the metal is in better condition for pouring than it was before. Owing to an accident, one ladle had to be held for twenty minutes after teeming and it was then found to be in better condition for pouring into ingots, than was a freshly teemed ladle of ordinary steel.

Virtually there is no segregation in steel ingots containing titanium. Segregation is caused by accumulations of phosphorus and sulphur combinations, with iron and manganese, carbides, etc., along the main axis of the ingot. Where the metal remains longest fluid, near the top, there will be the most segregation. Selective crystallization as the steel begins to harden and the lower specific gravity of these combinations are the two principal causes of this segregation.

The gases liberated from the steel as it cools and hardens, raise in vertical streams and carry up the specifically lightest elements. Selective crystallization entraps them as the metal cools and the top of the ingot will hold the most segregation. If these gases are made to combine with an element like titanium, which carries them into the slag, the steel will harden with practically no occlusion of gases. Then very little segregation can be present, as the force is removed which caused the specifically lighter impurities to rise and collect in the top of the ingot. Titanium steels are also practically free from blow-holes and the above described action of titanium is doubtless the reason.

If there is any titanium in the steel after the occluded gases have been removed it has a tendency to attack the sulphur and phosphorus and either counteract their injurious effects or remove them. The sulphur is reacted on and carried away to

the slag in the form of a sulphide, or sulpho-cyanide, of titanium. Special means have made the phosphorus pass into the slag as phosphate of titanium. Thus the mission of titanium does not seem completed after the oxides and nitrides have been removed.

Ferro-titanium has been used in all of the steel making processes, including the electric, and the metal has been made stronger and longer lived thereby. It was thought that the electric furnace steels would be made so free from gases of all kind that they would not need the service of any purifying element. This, however, has been proven erroneous, for titanium is now used for the removal of the last of the gases in electric furnace steels. It is less expensive and troublesome to use this material than to remove all of the occluded gases with the electric process. An exception must be made in the resistance electric furnace however, as steels made in that type are practically free from oxygen and nitrogen.

The abrasive or frictional wearing properties of titanium steel are well illustrated by the sections of 90-lb. rails which have recently been taken up after being in service for twenty months on the high-side of two curves, of practically the same curvature and grade, on the Lehigh Valley R. R. The average of a number of rails, measured at this same time, gave a ratio of wear of 1 to 1.54, in favor of the titanium treated rails. The deflection was 1.40 inches for the titanium and 1.56 inches for the ordinary rail.

All of the tests that have been given steels for endurance show that titanium greatly increases this property. In one test of open-hearth steel, on the White-Southern rotary vibrational machine, it withstood 2,660,000 revolutions before it broke. The same steel, treated with titanium, withstood 18,274,900 revolutions before it broke. Other tests such as impact, cold bend, alternating vibrational, compressive and tensile strength show an improvement when titanium has been properly added to the metal. Such encouraging results have been obtained with steels that a large amount of work is now being done on the brasses and bronzes so titanium can be successfully used in the non-ferrous field. It has been used for some time in copper and greatly reduces the blow-holes when casting this metal. Very good results have also been obtained when using it in iron and steel castings.

The production of gold, silver, copper, lead and zinc in the Western States and Alaska in 1911 has been announced by the United States Geological Survey in two advance chapters from Mineral Resources of the United States, 1911. Many interesting facts and figures are given showing the sources and distribution of the different metals. Milling processes produce over half the gold, while smelting produces over four-fifths of the silver. The report gives the ore tonnages and metal contents for the different districts in the various states. Copies of the reports may be had on application to the Director, United States Geological Survey, Washington, D. C.

The size of the feed to Chilean mills is an important factor in their operation and efficiency. According to Mr. G. A. Denny, *Informes y Memorias del Inst. Mexicano de Minas y Metalurgia*, Vol. III, No. 1, it is a wholly mistaken idea that a Chilean mill has a larger output if fed with fine material than with coarse. Contrariwise, it has a considerably higher output on ore fed from breakers set at 1.5 in. than on a pulp discharged from a 3-mesh screen, and probably four times the efficiency on the coarse feed cited than on ordinary middlings or tailings.

The effect of flotation on the world's supply of zinc was first noted in 1904, and in 1906 the spectacular rise in the production from Broken Hill began. Between 1906 and 1911 the production rose from 100,000 tons of concentrate to 500,000 tons. As a result of a statistical study of zinc production at Broken Hill Mr. T. J. Hoover is of the opinion that no further large zinc concentrating mills will be erected there, that there are no further large discoveries of new deposits or lodes in the district, and that the quantity of tailings now stacked is accurately known, as is the quantity being treated. He assumes that the production for 1913, 1914 and 1915 will be between 400,000 and 450,000 tons of concentrate per annum.

The Gayley Dry Blast Process*

By Prof. Henry M. Howe

Interesting as are the other aspects of the Gayley process, its greatest interest lies, I think, in the light which it throws on the nature of expert evidence and on the value of expert opinion.

What is this process? It is simply drying the air used for burning the fuel in the iron blast furnace, apparently a rather simple matter. To refresh your memory, the blast furnace is a huge vertical firebrick cylinder, roughly speaking. In it iron ore, which is essentially iron oxide, is converted into cast iron or pig iron by prolonged exposure to coke or its equivalent, in an atmosphere of mixed carbonic oxide, carbonic acid, and nitrogen, which results from burning this coke by means of atmospheric air forced in through appropriate openings near the bottom of the furnace, and called "the blast." The furnace is full from top to bottom of an intimate mixture of this coke and ore, together with limestone added for the purpose of forming with the barren mineral matter of the ore and with the ash of the coke a fusible silicate or slag, and for other purposes into which we need not enter here. These three solid materials collectively are called "the stock."

The burning of the coke generates at the bottom of the furnace a temperature so high as to melt away the bottom of this column of stock, or mixed coke ore and limestone, of which the last two have by this time been converted locally into metallic iron and lime, and as the column thus descends it is renewed at its top by adding more of this same mixture so as to keep the furnace continuously full.

There are, as it were, two rivers passing through this great cylinder in opposite directions, a sluggish river of solid stock which descends as its bottom is melted away, and a swift river of ascending gases resulting from the burning of the coke by the injected air or blast. The former traverses the length of the furnace in from 12 to 15 hours, the latter in a very few seconds. These rivers interact as they interpenetrate and flow past each other, the rising gaseous column progressively giving up its heat to the solid column and taking from that solid column the oxygen of its iron oxide, so that the gaseous stream as it emerges from the top of the furnace has taken from the descending ore all the oxygen that it is capable of removing, and has delivered over to that ore and its accompanying coke and limestone all the heat that they are capable of taking from it.

So much for the blast furnace process, which, like every mundane process that seems simple, is in fact of a complexity so overwhelming that the human mind is inherently and incurably impotent to grasp it. We rub our eyes and seeing as far as the ends of our noses, assume that we see to the end of the universe.

As a heat engine the blast furnace was known to be extremely efficient, as human heat engines go. Nevertheless by the extremely simple step of drying the blast Mr. Gayley made a further important saving of fuel amounting in some cases to 20 per cent, and according to our present evidence to about 10 per cent on an average, for usual American conditions. To those who had taken up the logical stick by the wrong end, such a saving by thus drying the blast seemed simply preposterous, as preposterous as talking a thousand miles through an iron wire, or waving a message to Europe without any wire, or as any invention is till you understand it.

Its preposterousness was promptly and convincingly exposed by the public spirited experts whose geographical misfortune prevented their knowing Mr. Gayley's character, though those of us more favored geographically followed "Br'er Fox" till our question "Why and how?" could be answered.

The heat required for heating and dissociating the moisture of the blast is a small fraction of the total heat requirement of the blast furnace process; how then dare we say that the

removal of this heat requirement may save 10 or even 20 per cent of the fuel?

Not a few of us had grown so used to calculating the heat needed for a given chemical and physical work like that of the blast furnace, and the heat evolved by the combustion of a given weight of fuel under known conditions, and to calculating thus the thermal balance, that we had lost sight of the supreme importance of temperature.

The atmospheric moisture, calorimetrically considered, is indeed slight, but thermometrically considered it is sometimes of overwhelming importance. As to its effect on climate Tyndall says "To say that on a day of average humidity in England, the atmospheric vapor exerts 100 times the action of the air itself, would certainly be an under-statement of the fact."

The sum and substance of it is that the blast furnace process has among its various duties to supply a certain quantity of heat at or above a certain high temperature, which for brevity we may call the critical temperature, while shamefacedly confessing that we are further overworking an already grossly overworked word. No quantity of heat offered at any lower temperature will do this work. All the heat in all the suns of the milky way, if offered at a temperature of 50 deg. C., could not boil one egg.

Drying the blast saves fuel by improving the temperature-distribution of the heat generated.

Perhaps this is more readily understood if we consider an imaginary case. Suppose that matters were so ordained that he who wished to build an iron building was obliged to take, along with his iron work, a certain fixed proportion of accessories, windows, flooring, tiling, etc., the proportion fitted for a ten-story building. That would be all well enough for those who build nine, ten, or eleven-story buildings; but for the builder of a forty-story building it would be most uneconomical, because whereas the quantity of accessories, windows, flooring, tiling, etc., increases directly as the height of the building, the iron work needed increases in a higher ratio; so that, in order to get enough iron work for his forty-story building he might have to get enough accessories for a sixty-story building, and the excess would be left on his hands. This is because of had proportioning of his supplies. A mere change in the proportion between iron work and accessories would cause a great saving.

It is somewhat so with a thermal process like that of the iron blast furnace. When combustion has raised the temperature above the critical point there is available first a certain quantity of heat above that temperature, the hyper-critical heat, and second another and larger quantity of heat below that temperature, the hypo-critical heat, the heat remaining when the temperature has sunk to the critical point. The hyper-critical heat is needed for certain work which can be done only at hyper-critical temperatures, the hypo-critical heat is available for work which can be done at hypo-critical temperatures; so that, as we have hyper and hypo-critical heat, we have also hyper and hypo-critical work.

For heat economy the hyper-critical heat should be to the hypo-critical at least as the hyper-critical work is to the hypo-critical work. This is indeed true of every specific temperature covered by the blast furnace process. The proportion between the two evidently depends on the temperature reached by combustion itself. The higher this temperature, the higher proportion does the hyper-critical heat bear to the hypo-critical heat.

If the temperature developed by combustion is so low that the ratio of hyper to hypo-critical heat is too low, is below the ratio of hyper to hypo-critical work, then in generating enough hyper-critical heat to do the hyper-critical work we are forced to generate an excess of hypo-critical heat over and above the hypo-critical needs of the process, and this excess of hypo-critical heat is used to poor advantage or is wasted. If my ratio of iron work to accessories is too low, then in providing my building with enough iron work for forty stories I am forced to provide enough of these accessories for sixty stories, and the excess is left on my hands. And as a mere change in

*Extracts from the address made by Prof. Howe at the presentation of the Perkin medal to Dr. James Gayley at the meeting of the New York section of the Society of Chemical Industry on January 24, 1913. An account of the proceedings, together with Dr. Gayley's address in full, was given in the February issue of this journal, page 71.

the ratio between iron work and accessories can enrich or ruin a builder, so a mere change in the ratio between hyper- and hypo-critical heat, induced by a change in combustion temperature, can lead to a wholly disproportionate change in the economy of our own vital processes or of the process of the blast furnace.

Thus it was with Neilson's introduction of the hot blast. Formerly blast furnaces were fed with cold air, with the result that, because of the low temperature of combustion, the proportion of hyper-critical to hypo-critical heat was far below the proportion of hyper- to hypo-critical work to be done, with the result that the burning of enough fuel to provide enough hyper-critical heat yielded a quantity of hypo-critical heat far in excess of the hypo-critical work to be done, and this excess was used to poor advantage or wasted. Hence raising the temperature of combustion by heating the blast led to a saving of fuel which, to those unable to think, was miraculous.

The degree of economy caused by blast-drying should vary from case to case with the initial lack of hyper-criticalness in the combustion temperature; and if there is no such lack initially, as may happen, then blast drying should cause no economy.

Other means of adjusting the ratio of hyper- to hypo-critical heat suggest themselves, such as raising the temperature of combustion by further preheating the blast, by enriching it in oxygen by removing part of the atmospheric nitrogen, or by electric induction at the very focus where the hyper-critical work goes on; and lowering the critical temperature by changes in the conduct of the process. We have not reached the end of knowledge in general, or of the improvement of the blast furnace process in particular. But the fact that blast drying, in removing the effects of the fluctuations in the atmospheric moisture removes a serious cause of irregularity in the working of the furnace and in the quality of its product, gives it an administrative and commercial advantage over other means of raising the combustion temperature which may well be decisive.

The deliberateness and caution, indeed the tardiness, with which the iron trade has proceeded in adapting dry blast is referable to various reasons, such as hesitation to incur the certainly great expense of its installation, the competition of other devices for increasing earnings in other directions, the wish of each to get the benefit of the experience gained by its earlier adopters, uncertainty as to whether the saving found by John Doe will apply to the different conditions of Richard Roe's furnace, and the like.

But, after all is said and done, that which interests us most is not the invention itself, important as that is, nor the great saving of fuel. The striking thing is the contrast between the mental attitude of the certainly very learned men of science who immediately stamped Mr. Gayley's claims as preposterous, and the attitude of this great Captain of Industry, who not only saw the saving to be effected but saw it so clearly that he was able to bring to pass the very costly experiments needed to prove his faith.

Let us learn the lesson of humility. Natural human caution is likely to prevent the cautious from saying "I know that so and so can be done" unless they do know it; but such cases as this show that it does not prevent even the well qualified, the expert, and the prudent from saying "So and so can not be done," though in fact it ought to prevent them, in view of the almost infinite excess of our ignorance over our knowledge.

*Columbia University,
New York City.*

The Utah Society of Engineers has recently secured new quarters in the Salt Lake Stock and Mining Exchange. The business office is in room 21, and the regular monthly meetings will be held in the large exchange room. The removal of the Society from its small quarters in the Newhouse building was necessitated by its rapid growth in the last few months. Mr. R. K. Brown is president of the Society this year.

Ore-Testing at the Colorado School of Mines

The Board of Trustees of the Colorado School of Mines has approved a system of charges to be made for the use of the experimental ore dressing and metallurgical plant of the school. Communications for further information should be addressed to the manager, William G. Haldane, Golden, Colo.

PRELIMINARY TESTS

The equipment consists of one 24-in. Wilfley table, one 4-in. by 6-in. two-compartment jig, one set hydraulic classifiers, one 6-in. by 48-in. amalgamating plate and one set of cyanide agitators. Lots of 10 to 75 lb. of ore are suitable for these tests. Price for each lot tested, \$25, including assays and analyses.

INTERMEDIATE TESTS

Small jigs and quarter-size Wilfley and Card tables. Lots of 100 to 1000 lb. of ore are desirable. Price for each lot tested, \$75, including necessary assays and analyses.

CYANIDATION

Preliminary cyanide tests will be made on lots of 25 lb. of ore. Price for each lot tested, \$30, including necessary assays and analyses. A detailed statement of results will be given, but the report will not embrace conclusions or advice. A consulting engineer should be employed to interpret the results and advise his client.

CARLOAD LOTS

In this work the full-size equipment of crushers, rolls, screens, jigs, regrinders, classifiers, tables and vanners may be used. These tests should be supervised by the customer's consulting engineer. The school does not assume responsibility for the results nor advise the adoption of any special treatment, but will place the appliances of the plant at the disposal of the consulting engineer. Charges will be from \$10 to \$100 per day for the use of such portion of the plant as needed.

DAILY CHARGES FOR USE OF PORTION OR ALL OF PLANT

Preparation and Sampling.—This includes weighing, crushing in Blake or Gates gyratory crushers, sampling by Vezin or Brunton samplers, and delivery of the ore to roll or stamp bins. Price, \$50.

Concentration.—Rolls, elevators, trommels, jigs, regrinding machines, classifiers, sand pump, tables and vanners. Price, \$50.

Amalgamation.—Stamp mill, with plate or inside amalgamation, classifiers, tables and vanners. Price, \$30.

Cyanidation.—Dorr classifier, tube mill, Dorr thickener, sand leaching tank, mechanical agitation tank, Paterson circulation treatment tank, pumps for sand, slime, solution and vacuum. Moore filter, Butters filter, zinc boxes and lead-lined acid tanks. Price, \$40.

Magnetic Separation.—Dings two-magnet separator with means of securing magnetic fields of high and low intensity. Price, \$10.

Magnetic Roasting.—Wilfley annular hearth revolving furnace, with pyrometers for temperature control. Price, \$15.

Electrostatic Separation.—Huff electrostatic separator, current-producing devices, and two types of separators for fine and coarse material. Price, \$10.

Use of entire plant per day, \$100.

ORE SHIPMENTS

Ore in small quantities may be shipped by Adams express to Golden, Colo. Larger lots should be sent by freight via Colorado & Southern Railway, or via Denver & Intermountain railway. All charges should be prepaid. Ore sent by freight must be hauled by wagon from the railroad to the plant at the shipper's expense. A deposit to cover all charges for ore treatment must be made in advance. When different tests are made on the same ore, only one charge will be made for assaying and analysis.

In gaging wire it is better to use a micrometer than either a disk or forked gage. The two latter are not as free from objections as the first. With a disk gage fine sizes of wire can be stretched in forcing the wire in the notch, while with forked gages it is possible to spring the gage to show wide variations. Neither the disk nor forked gage will give as close a measurement as the micrometer.

Annual Meeting of American Institute of Mining Engineers

Adoption of New Constitution—An Embarrassment of Riches in Professional Papers —The Symposium on Sound Steel Ingots

THE annual meeting of the American Institute of Mining Engineers, held in New York City on February 18 and 19, will go down into history not only as one of the most successful meetings from a professional engineering standpoint, but as the beginning of a new era in the Institute's history, as the result of the adoption of the new constitution.

On the evening of Monday, February 17, the members assembled for an informal social gathering at the Institute headquarters in the United Engineering Building. They listened to a gracious word of welcome by Dr. George F. Kunz and to a delightful address by the president, Professor Kemp, giving a sketch of the life work of the new president to be elected on the next day, Mr. Charles F. Rand, and enlivened by lantern slides in Professor Kemp's unique style which leaves the audience in constant reflection as to the extent of the genuineness of the photographs.

Business Meeting and Presidential Address

The morning session of Tuesday, February 18, was given over almost completely to the business meeting of the Institute. The chief result was the announcement that by the mail vote and the additional vote of those present the new constitution of the Institute has been adopted in the whole with an overwhelming majority, practically unanimously.

There was, however, an extra vote to be taken on four amendments by Messrs. Corning and Stone on minor matters, all of which were adopted, and on the provisional clause in the constitution providing for a special class of "Fellows" which should have the right to express an opinion with regard to pending or proposed legislation affecting the mining and metallurgical industries. The mail vote on the Fellows proposition showed a very slight majority against it (270 against the class of Fellows and 260 in favor of it). As this result could have easily been changed by the vote of those present, the Committee on Constitution, through Prof. J. W. Richards, explained that they had submitted the amendment concerning the class of Fellows by request and that they did not favor it now in view of the proposed union of the Mining and Metallurgical Society of America with the American Institute of Mining Engineers. Thereupon, the vote of those present was practically unanimous against the class of Fellows and a few who had voted by mail changed their votes, and the final joint result of the mail vote and of the votes of those present was 313 against the clause of Fellows and 258 for it.

Dr. Douglas in his warmly applauded report for the Land Committee stated that on the debt of \$68,000 there

had been subscribed already more than \$59,000, and urged those members who had not yet contributed to make up the small balance. This result seems to make sure that it will not be necessary to raise the membership fees, as with the land debt paid off the fixed charges of the Institute will be reduced by \$3,000 a year. Resolutions of thanks were voted to Dr. Douglas.

The result of the election of officers was then announced as follows:

Mr. Charles F. Rand, president of the Spanish-American Iron Company, was elected president.

Messrs. F. W. Denton, Karl Eilers, Sidney J. Jennings, T. H. Leggett, Waldemar Lindgren and B. B. Thayer were elected vice-presidents.

Messrs. J. W. Finch, James Gayley, J. A. Holmes, R. W. Hunt, John H. Janeway, E. P. Mathewson, W. J. Olcott, J. W. Richards, L. D. Ricketts, C. S. Robinson and E. L. Young were elected directors.

By the new constitution the secretary has ceased to be elected by the members at large and is being appointed by the Board of Directors. The proxies which had been made out were, therefore, not voted. The Board of Directors held meetings on Tuesday and Wednesday and during the afternoon session of Wednesday the new president, Mr. Charles F. Rand, brought to the members a "message from the Board of Directors," announcing that after several hours of consideration the Board had selected Mr. Bradley Stoughton for secretary.

The morning session of Tuesday was concluded by the address of the retiring president, Professor Kemp, which dealt with the subject of the ground waters in a very interesting manner. Lunch was then served and the reading and discussion of papers were taken up in the afternoon session.

Tuesday Afternoon Session

The papers presented in the afternoon session of Tuesday related to geology, mining and allied subjects.

The Role of Certain Metallic Minerals in Precipitating Silver and Gold

A paper by Dr. Chase Palmer and Dr. Edson S. Bastin, of the U. S. Geological Survey, was presented by Dr. Bastin and illustrated by experiments. The authors have made extended laboratory experiments on the rôle which certain metallic minerals play in precipitating silver and gold from solution and apply their chemical results to draw some interesting geological conclusions.

Their experiments show that certain sulphides, arsenides and sulph-arsenides of copper, nickel and cobalt precipi-

CHARLES F. RAND

President American Institute of Mining Engineers

tate metallic silver very efficiently from dilute aqueous solutions of silver sulphate. As the waters descending through the upper portions of most sulphide ore bodies are known to be sulphate waters, similar precipitative actions would be expected under natural conditions. The frequent association of silver in ore deposits with chalcocite and bornite, and particularly with niccolite and cobaltite, minerals which in the authors' experiments were among the most efficient precipitants, warrants the belief that such reactions are of great importance in secondary enrichment of ore bodies.

The more common sulphides such as pyrite, galena and sphalerite were relatively inactive as precipitants of silver from aqueous solutions of its sulphate.

The quantitative results obtained with niccolite and chalcocite indicate that the essential chemical changes in reactions of this type are due to oxidation through the hydrolitic action of water. It is apparent, therefore, that certain water solutions may act as potent oxidizing agents below the ground-water level.

The experiments indicated that nearly all of the sulphides and arsenides common in ore deposits were capable of reducing gold from a solution of its chloride, although important differences in the rapidity of the precipitation were observed with different minerals. Most of the minerals that are especially efficient as precipitants of silver are also effective precipitants of gold and a number of other minerals such as galena, pyrite, stibnite and millerite that are inefficient in precipitating silver are efficient in depositing gold.

It is known that the waters descending through the upper portions of sulphide ore bodies universally carry chlorides and it is probable that these chlorides have effected the solution of the gold. It is probable, therefore, that phenomena similar to those exhibited in the authors' experiments with gold chloride solution play an important part in secondary enrichment in gold.

While the phenomena described by the authors find their most immediate application in secondary enrichment it is perfectly possible that such reducing effects of the sulphides may be responsible in part for the primary association of the precious metals with certain sulphides in preference to others. It is recognized, of course, that certain mineral associations in ore deposits are probably the result of processes analogous to differentiation in rock magmas, but it is quite possible that other associations such as the apparent preference of gold for chalcocite and tetrahedrite rather than for pyrite in deposits carrying these three minerals may be due to differences in the reducing power of these sulphides themselves. Light could probably be thrown upon this point by the investigation of the reducing effect of various sulphides upon silver and gold salts dissolved in solutions having the composition of certain deep mine waters.

It is a generally recognized fact that the purity of alluvial gold is greater than that of the veins in the neighborhood. This superiority in fineness has generally been explained by the well-known fact that silver is more readily soluble in natural waters than gold, and is by them removed from the natural alloy, thus increasing its purity.

Mr Lindgren has recently discussed (U. S. Geo. Survey, No. 73, 1911) this matter at some length in a report on the Tertiary Gravels of California, and has presented a large amount of statistical data leading to the same conclusion. It has been thought by certain geologists that this refinement of the gold was accomplished by solutions circulating through the gravels themselves, but Mr. Lindgren states that "so far as the tertiary gravels of California are concerned, the conclusion of the writer is that solution and precipitation of gold have played an absolutely insignificant part."

Under the conditions of the experiments reported by the present authors it was found that nearly all of the

metallic minerals common in precious metal deposits were capable of precipitating gold while a much smaller number, and these not the most common ones, were active precipitants of silver. When it is remembered that the source of the placer gold is the oxidized zone of the original deposit and that the gold may have been dissolved and re-deposited several times within the vein before erosion carried it into the alluvium, it seems not improbable that such selective precipitation may be an important factor in this natural refining of gold.

A Microscope Study of Sulphide Ores of Copper

A paper by Dr. L. C. Gradon, of New York, and Dr. Joseph Murdoch, of Harvard University, Cambridge, Mass., was entitled "The Sulphide Ores of Copper—Some Results of Microscopic Study." The paper gives a very large amount of facts, experimentally established, and is illustrated by a series of thirty-six microphotographs of striking significance.

In the introduction the authors discuss the relation of scale in geologic work and the general characteristics of copper sulphide ores and outline the scope of their investigation. Then follow descriptions of the important minerals—pyrite, pyrrhotite, chalcocopyrite, bornite, covellite, chalcocite, enargite, tetrahedrite and tennantite. Each of these minerals is discussed as to primary character, alteration and secondary derivation.

Some of the more important conclusions are as follows:

Conclusion as to whether an ore or a given mineral in an ore is primary or secondary can be safely drawn in the great majority of cases from the type of structure involved.

In the case of chalcocite, internal or molecular structure as expressed in cleavage may also be used with caution as a criterion of the primary or secondary character of the mineral.

The following sulphide minerals common in copper ores are primary, i. e., they are products of original precipitation, probably from ascending, heated, alkaline solutions; pyrite, pyrrhotite, chalcocopyrite, bornite, chalcocite, enargite, tetrahedrite, tennantite, spalerite, galena, and probably covellite.

The following minerals are secondary, i. e., they are derived by the action of descending cold acid waters upon the other sulphides, i. e., secondary sulphide enrichment, chalcocopyrite, bornite, covellite, chalcocite and enargite.

The most important result of this study is perhaps "the abundant evidence afforded that primary copper deposits are definite, characteristic, clear-cut phenomena of striking similarity in the main, formed by well-defined processes as a result of certain specific causes acting through a limited and probably brief period of time. Among the ores that have been studied, at least, there are absolutely no indications favoring—rather, there is plentiful testimony against—the hypothesis that many or most ore bodies (excluding the enriched zone) are the result of 'repeated reworkings' of their constituents by various processes, of different causes, at separated times or over long extended periods. This idea, never ringing true nor supported by competent evidence, has served only to complicate and bfog the situation, and thus postpone universal acceptance of the fast-growing and now almost overwhelming proof of the direct and sole influence of igneous agencies in the formation of many ore bodies."

The following papers were also presented during the Tuesday afternoon session by their authors:

A Problem in Mining together with Some Data on Tunnel Driving. By F. M. Simonds and E. Z. Burns.

The Geographical Distribution of Mining Development in the United States. By E. W. Parker.

Electric Power Installation at El Tigre, Sonora, Mexico. By J. W. Malcolmson. (This paper contains some interesting figures of cost.)

Structure of the Northern Anthracite Basin Relative to Forms of Folds. By N. H. Darton.

Among the papers which were on the program for the afternoon, but which were read by title only, are the following:

The Hardinge Conical Mill. By **H. W. Hardinge**.

Fire Clay Deposits in Canada. By **Heinrich Ries**.

School Laboratory Work; the Sampling of an Ore Containing Coarse Gold. By **Charles F. Locke**.

In the evening a very interesting illustrated lecture was given by **Dr. Fred. Haynes Newell**, director of the United States Reclamation Bureau, on "Immigration and Its Relation to the Mining Industry." This lecture was greatly enjoyed by a large audience.

Symposium on Sound Ingots

The morning session of Wednesday was devoted to the reading of five papers relating to methods for improving the soundness of steel ingots and to a general discussion of the subject. There were some 200 members and guests

BRADLEY STOUGHTON

Secretary American Institute of Mining Engineers.

present, and the attendance was truly representative of the industries interested in sounder ingots. But the representatives of most of the big steel companies showed a rather regrettable reluctance to express their views. Nevertheless, the meeting was exceedingly interesting and profitable.

This symposium had been arranged by the Iron and Steel Division of the Institute, with Mr. Charles Kirchhoff, chairman, and Mr. Bradley Stoughton, secretary. As mentioned before, Mr. Stoughton is now also secretary of the Institute as a whole.

Piping and Segregation of Ingots of Steel and Ductility Tests for Open-Hearth Steel Rails

A paper by **Dr. P. H. Dudley** of the New York Central Lines on the above subject was first presented. It was an elaborate discussion of extended tests made on this subject.

Mr. Dudley called attention to the fact in the specifications for the New York Central Lines that in mill practice as soon as the ingots are stripped they should be charged into the reheating furnaces to prevent the setting steel to cool from its molten temperature to that of cold metal, and thus avoid the formation of the full shrinkage cavities in the ingots. It has been shown by the cutting of a large number of blooms that it is possible to prevent a shrinkage cavity from forming of not more than from 1.20 to 1.30 of the size in the top of the hot ingot by this method of good mill practice, of what would be formed by permitting

the ingot to become completely cold before it was put into the reheating furnace for rolling.

It is first necessary, however, to provide the hot molten metal with a chemical composition which will produce sound ingots and definite physical properties in the finished product. The first effort is to secure a well-deoxidized steel, and by proper mill practice make sound ingots.

Dr. Dudley does not consider it advisable to follow the suggestion of Mr. Talbot and Sir Robert Hadfield to use a large percentage of aluminium in the ingots to reduce more completely the oxides, in view of the difficulties already experienced with aluminium so used in rail steel for heavy wheel loads. "It would be better to use silicon or a combination of silicon and ferro-titanium to secure the desired results. We do not use as high percentages of silicon in steel as is employed abroad, except for tires."

Dr. Dudley then dealt at greater length with the segregation of basic open-hearth steel ingots, giving analytical diagrams of various ingots and finally discussed the drop and exhausted ductility tests for basic open-hearth steel rails.

Dr. Dudley's final conclusions for the manufacture of the present basic open-hearth rails are as follows:

"1. The chemical composition should provide for sound steel of ample physical properties of tenacity and toughness rather than hardness combined with brittleness.

"2. The impurities, phosphorus and sulphur, should be of minor content so the bath of metal can be purified to produce the large percentage of toughness and ductility due to the specified chemical composition.

"3. The ingot should have such relations of area of base compared to the height and weight that under good mill practice and suitable deoxidizers it can be made with controlled segregation, and only a trace of a shrinkage cavity in the top; then, when bloomed under its equalized initial heat, it is rendered pipeless by the usual 8 to 10 per cent discard.

"4. Aluminium can be replaced and silicon partly, as deoxidizers, with advantage by the use of ferro-titanium to purify, solidify and check segregation in rail, tire and axle steels, and also some of the lower grades of carbon steels where great purity is desired.

"5. The ductility and elongation tests to date furnish the best and only prompt means of determining the degree of purification of the steel per melt as it is made by indicating the physical properties secured before another melt is tapped from the same furnace, and are of decided advantage to the manufacturer as well as to the consumer. These tests are so advanced that they must be applied with knowledge and understanding for proper results, and not made mechanically for specified records.

"6. Every process or step of the entire manufacture of the steel, rolling and finishing of the rails, must contribute its part to secure the highest quality of the product incident to the chemical composition.

"7. Specifications should be drawn to indicate some of the major necessities of the consumer, and the tests and inspection conducted in a spirit to aid and invite the co-operation of the manufacturers to meet the progressive requirements in rail steel."

The Use of Anti-Piping Thermit In Casting Steel Ingots

The second paper of the session was presented by **Dr. E. A. Beck**, of the Goldschmidt Thermit Company, New York City. It deals with the interesting new application of anti-piping thermit for producing sound steel ingots. In contradistinction to an older method of using anti-piping thermit (in which a can filled with thermit was introduced into the upper part of the ingot and was intended to produce a heating effect), a new method has been more recently evolved in which the can with thermit is introduced as far down into the ingot as possible and simply a stirring action is intended proceeding from the

bottom to the top. This method has already been described in some detail in a paper by Dr. C. Canaris (this journal, Vol. X, page 232, April, 1912) and in a paper by Dr. Hans Goldschmidt (this journal, Vol. X, p. 739, Nov., 1912).

The application of the method is very clearly shown in Figs. 1 to 6, reproduced from Dr. Beck's paper and illustrating the different stages in the treatment of steel ingots with anti-piping thermit.

Fig. 1 represents a section of the mold filled in the usual way, either from the top or bottom. This mold

FIGS. 1 TO 6.—DIFFERENT STAGES IN THE TREATMENT OF STEEL INGOTS WITH ANTI-PIPING THERMIT

stands until a certain cooling off of the steel has taken place. The degree of the cooling can be determined approximately by watching the formation of the crust on the surface.

Fig. 2 shows how far the crust should extend before the introduction of thermit, in order to get the best results. In the case of a 5-ton ingot it takes about 7 minutes for the crust to form properly.

Fig. 3 shows the can introduced. The can is quickly pushed down through the steel to the bottom of the mold and kept there until the reaction is over. The resulting seething of the steel will last about 5 seconds.

Fig. 4 represents a cross-section through the mold after the reaction has taken place. The empty space which formed indicates that the steel has become denser.

Fig. 5 illustrates the addition of new steel. Care must be taken that the added liquid steel does not rise over the edge of the solidified crust.

Fig. 6 shows the treated ingot after the lid has been properly put on.

The advantages of this use of anti-piping thermit are due to I, improved quality, and II, better results in rolling.

I. Quality.—1. The steel becomes denser in proportion to amount of metal added after the thermit has been applied. The increased density is caused by the expulsion of the occluded gases due to the effluvia following the thermit reaction.

2. The removal of the already formed segregation toward the middle of the ingot and by their transfer to the surface of the ingot; further, segregations are avoided through equalization of the temperature of the steel.

II. Rolling.—1. Elimination of the laps which occur from piped ingots, or from ingots with a sunken or irregular head.

2. Better physical properties of the steel in the heads.

3. A saving of from 3 to 10 per cent of the finished

material will be obtained. An average of 5 per cent would give a profit of about 75 cents per ton.

4. Elimination of defective plates caused by large blow holes on secondary pipes.

5. In small ingots the cost of the treatment amounts to about 35 cents per ton in the open-hearth department; against this there is an estimated saving of about 75 cents per ton in the rolling department. In large ingots (about 8 tons and more) the cost of the treatment is only 20 cents per ton and the saving is the same as in a small one.

6. A still further saving, which could not be calculated exactly, will be derived from the decreased percentage of defective plates, which is cut down to about 0.3 per cent, according to Dr. Canaris. In this case all plates which do not give the required dimensions or have not the desired physical properties in the head are classed as defective. Untreated ingots of the same group are often not uniform. Frequently there is a sound ingot, which will give good results without thermit treatment, and next to it there may be one with a large pipe or blow hole. Uniformity is secured by the thermit treatment.

Commercial Production of Sound Steel Ingots

A paper by Mr. Emil Gathmann, of Baltimore, described his process for producing sound steel in an economical and hence commercial manner, which is adaptable to the production of practically all steel manufacturers, by readily effected rational changes in the methods of casting, cooling, and subsequent handling of the ingots.

The process is based on the observation that the freezing or solidifying of an ingot which has been practically deoxidized or, as the term is used, "killed" in the mold, depends entirely upon the shape of the horizontal cross-section of the ingot at its various planes from top to bottom, and also upon the thickness and consequent heat-absorptive power of various parts of the mold walls.

This fact is clearly brought out and in a series of photographs in Mr. Gathmann's paper. As a result of these facts observed in practice, Mr. Gathmann designed a metallic mold constructed to accelerate the cooling of the lower or greater portion of the molten mass and teemed ingot (approximately from 80 to 85 per cent) and to retard the cooling of the uppermost portion of the ingot, thus causing the upper portion to remain liquid longer and to act as a feeder. The upper portion of the ingot does not actually remain liquid much longer than in the usual practice for similar cross-sectional area, but as the cooling of the lower portion is greatly hastened a differential in cooling is obtained, which is really what is to be desired.

According to Mr. Gathmann's method it is essential that there be considerable lag in the cooling of the upper portion of the ingot compared with the time of freezing of the lower portion, hence, the distance from the vertical central axis of ingot is made much less at the bottom of ingot and progressively increases toward the top of the ingot. In crucible steel ingots, which are largely made in split molds, the actual sectional area of the top and bottom may remain practically constant throughout the length of the ingot, but the distance from the vertical longitudinal axis to the surface of the ingot progressively increases toward the top. In ordinary big-end-up practice, where sufficient taper or differential in distance from the vertical axis to the surface of the ingot is given, to accomplish any notable reduction in depth of piping, the actual cross-sectional area of lower part of the ingot is much less than that at the upper part, hence the depth of pipe is not the true index of the actual volume or weight of cropping necessary to obtain physically sound steel.

One of the advantages of the system or type of ingot is that it is possible to obtain a practically uniform cross-sectional area at top and bottom of ingot and still obtain the benefits of the big-end-up type of mold.

Lifting of segregation is generally conceded to follow the

reduction of pipe, and where the pipe is lifted the steel below undoubtedly becomes more homogeneous and freer from segregation.

For open-hearth practice with the big-end-up ingot, one of the greatest difficulties has been to devise a method of stripping and handling the ingots.

Fig. 7 shows the Gathmann ingot mold and stool on a car or buggy after teeming. The big-end-up mold will

FIG. 7.—INGOT MOLDS FOR PRODUCING SOUND CASTINGS

require a special type of stool to avoid such difficulties as might ordinarily be experienced in stripping, due to fins forming at the base of ingot and locking it to the mold. A downwardly tapered plug, $c-c'$, seals the base of the mold and projects through the stool, $p-p'$. When the teeming is finished the metal, by reason of the wedge-like taper at the lower portion of the ingot, is forced into virtual contact with the walls of the mold, which, due to the thickness of same, rapidly absorb the heat of the ingot. A slight differential or reverse taper of the ingot cavity is made from 15 to 20 per cent from the top of the mold. The ingot in shrinking will automatically provide an air space at this portion, thus breaking the contact of ingot from mold walls and retarding the flow or loss of heat from this portion of ingot.

Other illustrations in the paper, not reproduced here for lack of space, show a modification of the Gathmann mold for bottom-cast ingots, a stripper with provisions to suit the stripping of the big-end-up mold, and a slab ingot mold for plate or sheet mills desiring to roll directly from the ingots.

The author concludes that the general practice employing his process "reduces the pipe in the deoxidized or killed steel so that with an average discard of 12 per cent sound metal will be obtained.

"Segregation will undoubtedly be disposed of in direct ratio to the lifting of the pipe." . . . "This system is not in an experimental stage as many tons of steel are daily being cast in both open-hearth and crucible plants in accordance therewith."

Production of Solid Steel Ingots

A paper by Mr. Benjamin Talbot, of Middlebrough, England, with the above title was presented in abstract by Mr. Charles Kirchhoff.

It was essentially the same paper as presented by Mr. Talbot in a special meeting held on November 7, 1912, in New York, and reported in our December, 1912, issue (Vol. X, page 772).

To supplement the information given in that paper and reply to some criticisms made at the former meeting, Mr. Talbot had communicated the following remarks. In the discussion on his paper very great surprise was shown at the fact that in the sulphur prints exhibited there was a regular area of higher carbon and sulphur metal upon the inner wall of the solid envelope, and a purer center inside that.

The question was then raised whether this formation was regular when the ingots were treated uniformly, and doubts were expressed of its being consistently found. Further experiments have shown that it can be consistently relied upon, and there is no break in the formation of this structure.

A photograph of the structure of an ingot is given in the paper, showing a gradual gradation of one structure to another. Results of drop tests and tensile strength tests are also given.

"Assuming that a sound rail with this structure (a hard working face, harder ring at back of this, and softer center) is accepted by rail users, we have then to consider the practical adoption of the process in steel works. There is no doubt that for open-hearth steel rails the large 250-ton tilting furnaces, giving heats of from 50 to 60 ton, irrespective of how the furnaces are operated, can give the steel in a more regular sequence, and are under better control as regards time of tapping than the so-called 60-ton fixed furnaces.

"As to the casting department, I may say that in my opinion the present ordinary methods have to be revised, and the casting must become an important department of steel manufacture. To-day both metallurgists and works' operators have neglected this department, and have not considered it as of anything like the same importance as the actual manufacture of the pig iron, or the conversion of the iron into steel.

"There is no doubt that the railway engineers have hit upon that point in the manufacture of steel rails which is causing most defects, and if given sound ingots the troubles now encountered in rail manufacture will be avoided. To my mind the casting department should have the attention of men skilled in the art to remove the slur now put upon steel makers in reference to cavities and blow holes, which form in the ingot during the solidification of the steel in the mold.

"I fully realize that if liquid compression of the ingot is to be adopted steel furnaces must not be allowed to 'bunch' together, and to tap a large number of heats at once as is the present practice. If a continuous set of rolls be used for liquid compression, then such rolls must be equal to dealing with the maximum quantity of steel tapped in any given time, but speaking as a work's engineer and practical operator, I see no difficulty in designing a plant to squeeze the required number of ingots to keep a modern rail mill supplied.

"Assuming that the necessary preparatory treatment has been made, we find that the size of the ingot must be standardized when such treatment is used and a 4-ton ingot seems to be a most useful size in this respect.

"Finally, in my opinion, the characteristic structure developed in rails treated by my squeezing process must cause these rails to be better than rails from the upper portion of ingots from ordinary heats which are always more or less segregated in the center."

Heating the Top

The Hadfield process for producing sound ingots by heating the top in a special manner was the subject of a paper by Sir Robert Hadfield, presented by Mr. Henry D. Hibbard.

Sir Robert Hadfield's process was described and illustrated in our November, 1912 issue (Vol. X, page 738), and his arrangements for applying the method on a large scale were described and illustrated in our February, 1913, issue (Vol. XI, page 79).

Mr. Hibbard gave an outline of the process, and exhibited a great many photographs and diagrams.

Comparative Notes on Steel Rail Rolling

A paper by Colonel Robert W. Hunt, of Chicago, Ill., was available in mimeographed form.

"I have frequently stated that while the chemical composition of steel was important, yet even greater importance was connected with the mechanical and heat treatment of the metal. During the past year I encountered such a positive example of that fact that I deem it worth putting upon record.

"A prominent railway system divided an order for open-hearth steel rails between two steel works, both of which are under the control of the same corporation, giving to one about 18,000 tons, and to the other 7500 tons of the same section and to be made under the same specifications. The rolling results obtained in two mills varied so widely that a study of the figures is intensely interesting and serves to illustrate the advantages obtained by careful ingot casting, and quite as pertinently the possible benefits of careful subsequent heating and rolling with moderate reductions in the rolling process. The smaller order was rolled complete in four installments during the same months that the larger order was being made in eight separate installments; but, to permit of exact comparisons, the totals of the four installments (completing the order with the mill which I will call A) are given with the totals of the first four installments of the larger order, made by the mill designated as B. These rolling results are:

	Mill A.	Mill B.
Number of rollings.....	4	4
Total number of rails rolled.....	18,278	27,832
Percentage of rails cut to short length because of flaws near ends, etc.....	0.7	7.6
Percentage of rails made second quality for flaws, etc.....	0.9	6.3
Percentage of rails scrapped for flaws, etc.	0.6	4.5
Percentage of rails scrapped for failure at drop test	none	3.4

"It should be stated that the figures above shown cover all the reasons for putting the rails in the classes stated. Thus a part of the percentage of rails cut to short lengths may have been because of bad drilling or bad sawing. Such classification, however, in this case is entirely proper, as neither mill suffered from unusual or abnormal difficulties in any way, and the figures indicate ordinary performance uninfluenced by unusual errors of either workmanship or mechanical troubles in rolling.

"Emphasis should be laid on the fact that both mills were working to exactly the same specification, and producing a section which has been in use for several years and in large tonnage. It is an 85-lb. one, having 36.7 per cent of metal in the head, 22.2 per cent in the web and 41.1 per cent in the base, being, therefore, well proportion for the avoiding of torn flanges or other rolling difficulties sometimes encountered with sections having thin flanges."

The chemical composition and drop test specified with average results obtained in the two mills are given in the paper. Both mills took advantage of the full range permitted in the chemical compositions. Though with respect to obtaining consistent carbon results, the results of mill

A were more consistent than those of mill B, the "chemical composition obtained at the two mills agrees so closely that some other reason must be sought to explain the divergent physical results obtained in the product, and, therefore, data on the actual performance of the mill operations is important."

This is given in form of various tables in the paper.

It appears that "both mills were casting large heats, approximating 85 tons. These were made by almost identical methods of the usual scrap and pig-iron process, the iron taken from mixers, as required, and varying in proportion to the scrap used. As far as possible, at both mills, this mixer metal was used for recarbonizing in the furnace, but many heats had coke or coal added to the ladle on tapping, in addition to the usual ferro-manganese and ferro-silicon. While the heats at mill A were slightly larger than at B, the difference is not of importance, but it is pertinent to note that there are but six furnaces represented at mill A, as against 27 which furnished the rail steel at B; and, consequently, there were probably but two steel melters working at A, as against at least six at B.

"The personal equation may, therefore, have played an important part in making the steel.

"Equally noticeable is the fact that while the average for the time intervals of the various operations at the two mills is not much different, still the range between the maximum and minimum for B are consistently greater than for A.

"There can be but very little doubt that a delay between casting and stripping ingots and between stripping and charging in the soaking pits is likely to be seriously reflected in the soundness of the ingots, and of at least equal importance is the necessity for teeming the steel at uniform temperature. A variation of 50 minutes in the time heats were held in the ladle prior to casting must have caused variable teeming temperatures and produced many blow holes in some of the ingots. Admitting the presence of blow holes near the surface of the sides of the ingots, and remembering the oxidizing action in the soaking pits, it is not surprising that heavy reductions in the blooming mill had an extremely detrimental effect on the product.

"This is reflected, no doubt, in the large number of rails found containing flaws at mill B.

"Appreciating, therefore, the probable difference in the ingots produced at the two mills and the actual difference in the blooming practice, the principal other variable existing was in the reheating of the blooms at mill A. There the ingots were cut into four blooms, which were then given a wash heat in reheating furnaces after which they were rolled into two rails in a rail train of eleven passes. At mill B the rail train consisted of nine passes with no reheating of the blooms."

The reported history of the heats rejected at mill B is also given, together with analyses of the rejected heats.

Two heats were rejected at the drop test because two of the three test pieces broke on the first blow of the tup. The steel of the first heat was reported as being somewhat low in temperature when tapped. While pouring, the nozzle froze up and while the ingots were in the soaking pits an average of four hours and twenty minutes, they bloomed cold and rough. The second heat was quite the opposite, the tapping temperature being high and while casting the stopper head was finally lost, but the heating and the blooming were normal.

Four heats were lost at the drop test, because they exceeded the deflection limits. On the first, all conditions were reported normal, save that the ingots were held in the pits for an average time of 24 hours. The second heat tapped cold, the pouring nozzle froze, and the ingot tops were spongy. The third tapped hot, but otherwise, like the fourth, had normal conditions.

General Discussion on Sound Ingots

A general and quite extended discussion on improving the soundness of ingots followed.

The following four questions on piping had been formulated by the committee of arrangements as a basis for the discussion:

1. Is the present method of getting rid of the pipe by cropping a safe and reliable device for making sound steel?
2. Is it desirable to increase the amount of metal arbitrarily cropped off the top of an ingot, and if so what would be a fair excess price to pay for cropping off 20 per cent?
3. Is it commercially practicable to make ingots without pipes or blow-holes and what addition of expense of manufacture would be justified to accomplish this result?
4. What process for making pipeless ingots seems the most promising of commercial success and why?

Dr. A. Sauveur, of Harvard University, opened the general discussion by referring to the fact that years ago he had pointed out how great a source of danger the pipes in ingots were for rails, but his word of warning had met only with opposition and it had been said that the pipes would be welded in manufacture of the rails, etc. It was a great advance that now both rail makers and railroads were willing to admit the danger. If the processes for producing sound ingots, described in the preceding papers, are right or if any one of them is right, there will be no more excuse in future.

Mr. Robert Job commented on the questions which were the basis of discussion. He pointed out that with good mill practice very little piping is present, while with poor mill practice 50 per cent discard might not produce sound rails. For this reason the question (2) where it is desirable to increase the discard of metal arbitrarily should be answered without hesitation in the negative. Such practice would simply penalize good mill practice. Tests should be made to detect piping in any ingot to be used for rail steel. The tests of the Lehigh Valley Railroad were described. A confirmative answer was given by Mr. Job to question (3) whether it is commercially practicable to make ingots without pipes or blow-holes. He pointed out the need of thoroughly deoxidizing the steel; soundness presupposes deoxidation.

Mr. Max H. Wickhorst, engineer of tests of the Rail Committee of the American Railway Engineering Association divided rail failures into head failures (split heads), base failures, and "broken rails" (square or angular breaks). The first class—that of head failures—makes up one-half of all the rail failures and is due to the interior condition of the ingots from which the rail was made. Segregation is the source of the trouble. Segregation must be distinguished very sharply from piping. Silicon, titanium, aluminium reduce segregation. When they are used, the ingot shows a deep pipe, but less spongy condition. The origin of split heads of rails is not piping, but the condition of segregation. We need not be so much afraid of the pipe itself, but rather of segregation. If this is avoided 50 per cent of all the rail trouble is solved.

Mr. L. E. Howard, of the Simonds Manufacturing Company, described a method of his own used successfully by his company in crucible steel practice. The process employs essentially lateral compression. Two sample ingots showing the successful suppression of piping were exhibited. In reply to question three he pointed out that his method was a commercial success, as the average cost including everything is less than 3 per cent of the cost of the ingots. For ingots of larger size his method must be somewhat modified.

Mr. J. E. Sague, engineer of the Public Service Commission of the Second District, summarized the chief results of the report which he had made as a result of the inquiry into the limits of the rail failure proposition. He found that from the accident standpoint the failure of rails is very much exaggerated in newspaper discussions. Nevertheless, as it really is, it is a grave proposition and a great deal more

knowledge is necessary on the subject. As far as the steel maker is concerned, the start must be made at the ingot. One cannot expect sound rails, except when starting with sound ingots. But the railroads have also their own problems to solve. It is a great advance that the fact has been recognized that a rush from New York to Chicago in 18 hours is not safe under any and all conditions of weather. To have their trains arrive on time, not to rush them through in the shortest possible time, should be the ideal of railway managers. In the whole there is no reason for despair.

Mr. Henry D. Hibbard, of Plainfield, N. J., commented at some length on the Hadfield process and then made some remarks on segregation. The problem is probably more serious than usually imagined. The segregated material heretofore used for analysis is probably always diluted by admixtures.

Mr. James E. Howard pointed out that in the first few passes there is evidence of elimination of the possibility of pipes and blow-holes. But what cannot be eliminated at all are particles of slag, etc., disseminated through the steel. Against them there is no correction. It is most important that these minute slag inclusions should be avoided.

Mr. W. C. Cushing, of the Pennsylvania R. R. Co., said that question (2), whether it would be desirable to increase the amount of metal arbitrarily cropped off the top of an ingot, should surely be answered in the negative. Progressive discard upon examination of soundness of the ingots seems to be the best at present. As to the statistics of rail failures in the United States head failures are 60 to 70 per cent of the total failures, web failures 5 per cent, base failures 5 to 10 per cent, broken rails 20 to 25 per cent. The rail failure statistics of the United States includes all these failures, not simply broken rails, as European critics have wrongly assumed. It is the broken rail that gives the most trouble and thought. Mr. Cushing asked finally as to the relative efficiency of aluminium, silicon and titanium as deoxidizers.

Mr. G. H. Clamer, of the Ajax Metal Company, described an electric device based on the principle that if the top of the ingot is kept hot, no piping will take place. There are different methods possible for keeping the top hot. The device described by him makes use of the pinch effect (as in the Hering electric furnace). It consists chiefly of a magnesia block with a cavity and a narrow channel connecting this cavity with the outside. This block is placed into the metal at the top of the ingot so that the steel enters the block through the channel. By providing suitable steel electrodes with connections to a small transformer an electric current is passed through the metal, the pinch effect is produced in the channel, and a heating and circulating effect is obtained as in the Hering steel furnace.

Dr. A. S. Cushman, of Washington, D. C., spoke on the extended investigation which is to be carried out under his direction by the American Rolling Mill Company. No final results have yet been obtained, but a special ingot splitting apparatus has just been installed and with this facility it is hoped to get decisive results as to the effectiveness of the different methods.

Mr. N. Petinot, of the Titanium Alloys Manufacturing Company, first dealt on the significance of some of the segregation analyses mentioned in Dr. Dudley's paper. He then discussed the relative efficiency of aluminium, silicon and titanium as deoxidizers. While all three remove oxygen, the results of the deoxidizing reactions are different. Aluminium is oxidized to alumina and the alumina particles are liable to remain disseminated in the steel and cause trouble. Silicon forms silica, silicides, silicates. With titanium on the other hand titanate acid is formed which rises to the top and is eliminated. Silicon should be used moderately and should be followed by titanium which will not only complete the deoxidation but will remove the iron silicates. Dr. Dudley, later in the discussion, confirmed the efficiency of titanium as a deoxidizer.

Prof. Henry M. Howe discussed the reason why pipes are formed at all and emphasized that it was all important to let solidification of the top lag behind the solidification of the bottom. Millmen have not gone to the limit in this respect. To cast from the bottom is worst in this respect, to cast from the top with the large end up is the best. There are special methods of heating the top, but they represent necessarily some expense. But the same result may be obtained by purely administrative methods. As to pouring, it may be asked whether it is possible in pouring to fill first only part of the mold and then come back a little later and pour again and fill up the top. As to the possibility of this, millmen may say no; but if yes as answer is at all possible, it would be well worth while trying it. In the whole purely administrative methods may perhaps prove just as good as special and more expensive processes.

Mr. K. W. Zimmerschied, of the General Motors Company, divided the troubles which remain in the steel from the ingot, into pipes, segregation, and enclosures of non-metallic material. Pipes cause the smallest trouble, the enclosures of non-metallic material (oxides of iron and manganese, alumina, etc.) cause the most trouble. To avoid them is a more important problem than that of piping. If aluminium is used as a deoxidizer properly, the alumina, though solid, will probably rise as quickly to the top as titanium oxide on account of its much lighter weight.

Mr. Zimmerschied then took up the four questions which formed the basis of discussion. Question (1), whether the present method of getting rid of the pipe by cropping is a safe and reliable device for making sound steel, he answered with yes. In reply to question (2), whether it was desirable to increase the amount of discard arbitrarily, he said that this was out of the question. Question (3), whether it is commercially practicable to make ingots without pipes and blow-holes, he answered with yes and added that the amount of the additional cost was a commercial consideration depending on the circumstances. As to question (4), what process for making pipeless ingots seemed the most promising of commercial success, he said that the cure must be a continuous one and must progress from the bottom to the top. In conclusion he made what he called a "wild suggestion": with our advance in cutting methods, why not split every ingot before you roll it?

Mr. Henry Hess, of the Hess-Bright Manufacturing Company, described some experiments made by himself with a method used formerly in a similar way by Professors Howe and Stoughton. To look into the interior of an ingot while in course of solidification, he made solidification experiments with resin in test tubes. He could form pipes of any form and at any place by changing the method of heating the test tube. Where you heat it, and where you heat it last, there you get the pipe.

After conclusion of the discussion lunch was served in an adjoining room.

Wednesday Afternoon Session

Mr. John Birkinbine presided during the afternoon session. A paper by Mr. James R. Finley, of New York City, on the "valuation of iron mines" was read, in the absence of the author, by Mr. Stoughton and discussed by Messrs. Birkinbine, Norris, and Parker.

Dr. Albert Sauveur, of Harvard University, then presented a paper entitled "Notes on Cast Iron," with special reference to the recent paper of Mr. J. E. Johnson, Jr. We reserve an abstract of Dr. Sauveur's paper for a future issue. The paper was discussed by Dr. Howe and Dr. Moldenke.

Dr. Henry M. Howe, of Columbia University, then presented his paper, "Why does lag increase with the temperature from which cooling starts?" We reserve an abstract for a future issue.

Sintering Iron Bearing Materials

A paper by Mr. B. G. Klugh, of Birdsboro, Pa., on "The microstructure of sintered iron-bearing materials" was read, in

the absence of the author, by Mr. Arthur S. Dwight and illustrated by a long series of lantern slides of structural photographs. The chief results of the paper are as follows:

The permeability of the cell-wall of a sintered product varies, inversely, as the degree of fusion to which it has been subjected.

In a product of complete fusion, the silica present combines with its equivalent of iron oxide to form a perfect glass which, from its greater fluidity, envelops and seals up the remaining iron oxide from the action of gases.

Conversely of the foregoing conclusion, in the product of the lowest degree of fusion, the iron oxide and slag-forming materials as a unit are bonded together by incipient fusion, leaving the predominant iron oxide, free and vulnerable to the action of the gases, in the highest degree attainable in solid products.

The above salient facts show that the Dwight and Lloyd products when properly made, do possess those properties which distinguish it from the products of other sintering processes or agglomerating methods, by freedom from those constituents, to which scouring action in the blast furnace is attributed.

New Design of Open-Hearth Steel Furnace Using Producer Gas

Mr. Herbert F. Miller, Jr., of Verona, Pa., in his paper on this subject, expressed the opinion that the gas and brick costs of open-hearth furnaces using producer gas could be greatly decreased by a change in the design of the port, which would materially reduce the first cost of the furnace, the rebuilding cost, and the repair cost.

He first outlined the defect of the present design and then described two new designs, both of which involve the same principle of putting a single air uptake directly back of the gas uptake as is shown in Figs. 8 and 9.

In Fig. 8 the port has about one-third of the width of the hearth, whereas the present type has the full width. The roof of the port dips sharply, compressing the air down on the gas; and the roof of the hearth is gradually dropped to meet it.

The gas-port arch is retained although flattened to the width of the port. The end C is from 6 to 10 ft. from the edge of the bath.

There is a small seal-door on each side of the port at C to permit the repair of the port or the removal of the brick which might fall from the gas-port arch.

The point C will move back slower than in the present type, because it will be less exposed to the flame, which will always be under the air.

The possible defect of this design is that when the gas-port arch has become short, combustion will commence too far from the bath, and make a high gas cost. Another objection is, that this design could not be applied to existing furnaces because their ports would have to be lengthened considerably. If the flame in the above design can always be controlled, even when the gas-port arch has burned back to the gas uptake, why have a gas-port arch at all?

The design shown in Fig. 9 is the solution. Here it will be seen that the furnace is similar in outline to the present open-port type in use at Homestead. The air uptake A is back of the gas uptake, from which it is separated by a substantial wall. The gas uptake, which is as wide as the port, is from 6 to 10 ft. from the bath. The port is open and smooth, narrow and low. The small cross section of this port assures a speedy union of the preheated air and gas, resulting in a short flame of intense heat, which will be under control throughout the run.

FIG. 8.—PART OF O. H. FURNACE USING PRODUCER GAS

Some may think that the gas rising at right angles to the air will make a high flame. If the port is low enough this will not occur. The author has put a stream of air having a pressure of 70 lb. per sq. in. under a natural gas flame, and found that there was very little deflection of the flame.

This design could be applied to the present type of producer-gas furnaces. The only alteration of importance would

be a reversal of the gas checkers from the outside to the inside position.

In building a new furnace, a great saving of brick would be made in the ports, as can be readily seen.

Repairs to the dividing wall can be made through small seals by the side of the gas port. The flame will always be under control and the furnace should slow up only because of dirty checkers and insufficient draft. Natural gas could be used if desired by introducing it as usual at the sides and in

FIG. 9.—PART OF O. H. FURNACE USING PRODUCER GAS

front of the uptake *G*. In the author's judgment, the adoption of this design would do away with much of the trouble and expense attending the present type of producer-gas furnace and greatly decrease the operating cost.

In the discussion Mr. Hibbard questioned whether with this design a good spreading of the flame over the hearth could be obtained. Mr. Miller replied that the design worked well with natural gas.

The last paper on the program was presented by Mr. F. L. Grammer, of Leesburg, Va., on "Blast furnace slag analyses for 24 hours."

The meeting then adjourned.

Notes on Chemistry and Metallurgy in Great Britain

Institution of Mining and Metallurgy

At the third general meeting of this Institution, held at the rooms of the Geological Society, Burlington House, on Dec. 19, three papers of unusual interest were discussed together, as all bearing upon questions connected with tin metallurgy. These were Mr. W. Fischer Wilkinson's "On the Dressing of Tin Ores in Cornwall," Mr. H. J. B. Rawlin's "Notes on the Direct Volumetric Determination of Tin," and Mr. R. T. Hancock's "Notes of the Valuation of Nigerian Tin Concentrates."

Mr. Holloway, who opened the discussion, pointed out that as Mr. Rawlin's paper dealt entirely with the analysis of metallic tin, it might at first sight appear to be more a paper for an analytical society than for themselves; but that it was important in connection with the chemical testing of the metallic tin obtained by such methods as the old Cornish, or culm method, or the more modern cyanide method of determining tin in black tin concentrates. Mr. Wilkinson's paper related entirely to Cornish tin dressing. Mr. Holloway was sorry to see heavy Californian stamps so largely used in Cornwall. The recovery of the tin was rendered less direct by the use of heavy stamps.

The discussion generally treated of the most correct method of estimating the recovery, and the applications of the chemical assay and the "vanning" test. Mr. E. S. King said that he found the only way to get at the correct extraction was by the chemical assay of the heads and the output of pure black tin. The tin account was kept in just the same way as a gold account; on one side was entered so many tons of ore containing so many tons of black tin; against that they had the amount of pure black tin sold. This was at Carn Brea.

With reference to the vanning assay, he said the most obvious explanation of tin which escaped from the vanning and was

caught by the wet assay was the smallness of grain of cassiterite in the tinstone. It should be remembered, also, that there were tin-carrying minerals other than cassiterite.

Mr. Josiah Paull estimated the recovery at the mine with which he was connected at 78 per cent to 80 per cent. Mr. Wilkinson had given the average for Cornwall as something like 50 per cent to 55 per cent. His results were from samples of pulp from the screens taken practically every hour throughout the twenty-four. Afterwards replying to Mr. Flowers, Mr. Paull modified his percentage by a small allowance for wet weight.

Mr. H. L. Twite, in a written communication, pointed out the importance of even 1 per cent in recovery. He had known samples sent to two different assayers and the difference in the assays returned was 0.3 per cent, which was repeated on several assays.

Mr. Amos Treloar gave the recovery for the Carn Brea and Tincroft plant, one of the oldest and most out of date in Cornwall, as 73.7 per cent. Mr. Frank Merricks inquired if Mr. Paull, in his figure of 78 per cent to 80 per cent of recovery at South Crofty, meant a 62 per cent extraction?

The irregularity of results quoted and the disagreement between the figures obtained on assay and test show how extremely difficult it is to obtain a standard method of sampling and testing which would admit of exact comparison.

Oil Fuel

An example of the growing interest in oil fuel in British scientific circles is afforded by the lectures on the subject delivered at the Society of Arts by Prof. Vivian B. Lewes (Cantor Lectures). On the question of oil fuel for power purposes, the professor noted that the method of obtaining the heat from the fuel had evolved into spraying the oil into the furnace, with a swiveling motion to the cloud formed, thus retarding the passage through the furnace and combustion space, so as to give sufficient time for complete combustion. When used as a fuel for raising steam, petroleum might be taken as having an evaporative power, weight for weight, 50 per cent higher than Welsh steam coal. It was known that 0.5 lb. of water evaporated was the best duty which could be obtained per pound of coal, which is a difference of 4.5 lb. from the calculated amount, due to losses of heat. Allowing the same ratio of loss for the oil fuel, the evaporative duty should be 13.2 lb. in practice, or even higher, according to the type of boiler and length of time under steam.

With regard to the internal-combustion engines, taking the highly efficient Diesel engine as an example, in spite of its only consuming one-third of the weight of fuel used by the best over-type superheated condensing steam plant, yet for a given power with coal at 18/- per ton and oil at 42/- per ton, the annual cost of running the steam plant would be less than that of the Diesel engine when all items of expense were taken into consideration. On surface combustion, Prof. W. A. Bone had found that when a mixture of a combustible gas with air was forced under pressure through a porous diaphragm of asbestos and fireclay, if the mixture were ignited as it leaked through the porous mass, it could not explode, but burnt on the surface of the diaphragm and quickly raised it to a very high degree of incandescence. This had been adapted for practical work with a boiler, and a very high efficiency had been obtained.

Steel Metallurgy

"Recent Advances in Steel Metallurgy" was the subject of a lecture delivered at the Royal Institution by Prof. J. O. Arnold, of Sheffield, in January. After noting the improvements in steel for cutting tools introduced by Mushet, and other modifications of the same process, involving the use of tungsten, the lecturer goes on to the introduction of vanadium steels in 1800-1902. The addition of about 0.6 per cent of vanadium to a pure carbon steel containing about 1 per cent of carbon raised the yield point from 35 to 65 tons per square inch, and the maximum stress from 60 to 80 tons, the elongation being 7 per cent, and the reduction of area 8 per cent.

According to researches made by the lecturer and Prof. A. A. Read, of the University of Wales, vanadium did not seem to form a double carbide with iron. It gradually wrested the carbon from the carbide of iron till when about 5 per cent of vanadium was present Fe_3C could not exist, and only a vanadium carbide V_4C containing 15 per cent of carbon was present, this constituent being constant at any rate in tool steels containing up to 14 per cent of vanadium.

Strains in Metals

Attention is called by Mr. T. Vaughan Hughes, A. R. S. M., in the *Electrical Review* to strains set up in the manufacture of copper and other metallic parts, such as condenser tubes. He advocates that at least two causes of failure of metals and alloys under the control of the makers should be removed, namely (a) uneven heating appliances and (b) antiquated heat treatment in chemically and physically active atmospheres.

Oil Explosions in Transformers and Switches

Two remarkable accidents, accompanied by fatal consequences, recently occurred at a main transformer station of the Victoria Falls & Transvaal Power Company. The station takes current at 40,000 volts from the trunk lines and transforms down to 20,000 volts with oil-filled transformers, the oil being cooled by constant circulation of cold water through pipes. "Expansion tanks" are attached to and above the transformers to ensure their being always filled with oil and to receive any outflow resulting from increase of volume of the oil when its temperature rises.

While a thunderstorm was in progress there was a "surge" on the main which broke down one transformer with the result that it was cut out. Three attendants examined the transformer and one of them, wishing to see the level of the oil in the tank, held a lighted match to the aperture at the top, when a violent explosion occurred which killed one man and severely injured the two others. It appears, too, that instantly after the explosion a large quantity of oil was ejected from the tank and set the transformer in a terrific mass of flames.

About a week later another explosion took place at the same station in a 20,000-volt oil switch controlling some low-voltage apparatus. The cause is attributed to a "surge" on the 20,000-volt lines which discharged across the busbars and made the oil switch trip; and the instantaneous effect was that a strong fireproof dividing door was burst open, a man at a telephone in the adjacent room was enveloped by the vast mass of flame and died soon afterward and others were seriously burned.

The commonly accepted explanation of the first of these explosions is that arcing, resulting from a "short" in the transformer, decomposed the oil with liberation of hydrogen or gaseous hydrocarbons, such as methane, or perhaps a mixture of these gases, which, rising into the expansion tank, formed an explosive mixture with the air therein. A similar explanation has also been offered for switch explosions. But in both cases the intense and rapid combustion of the ejected oil—which would, of course, originally have a high flashpoint, probably not lower than 160 deg. C.—suggests that there may also have been some action analogous to "cracking" which split up the higher liquid paraffins into paraffins of considerably lower density and flashpoint together with some olefins.

A chemical examination of the residual oil might throw some light on the question, which manifestly deserves more thorough investigation than it has yet received.

Detection and Estimation of Carbon Monoxide

Two methods of determining small percentages of carbon monoxide in air have recently been communicated to the Académie des Sciences of Paris. MM. A. Lévey and A. Pécoul adopted a suggestion of M. Armand Gautier and have found that the reduction of iodic acid by carbon monoxide between 60 deg and 80 deg. C. affords a means of detecting one part of the gas in 200,000 parts of air and yields accurate quantitative results. Three liters of air are passed from the aspirator into a vessel containing iodic acid and maintained at a temperature of about 70 deg. C., the iodine liberated is absorbed by chloroform, and its amount is determined colori-

metrically against solutions of iodine, of known strength, in chloroform. The authors have successfully applied this process to the examination of air in Paris schools, hospitals and railways.

The other method, described by M. Guasco, is an application of the well-known fact that platinum black absorbs combustible gases, and especially carbon monoxide, with evolution of heat. It differs from earlier proposals to utilize this phenomenon for the estimation of carbon monoxide in the employment of a Leslie differential thermometer, one bulb of which is coated with platinum black, while both bulbs are protected by porous envelopes preventing direct access of air, but permitting osmotic penetration.

It is obvious that M. Guasco's apparatus can only be relied on when the air is ascertained to be free from combustible gases other than carbon monoxide. An apparatus on the same principle was devised by Messrs. J. Pitkin and T. Niblett in 1889; but they used two ordinary sensitive thermometers, side by side, one having the bulb coated with platinum black, and the instrument was not sufficiently sensitive for the estimation of less than about 1/10 per cent of carbon monoxide in air.

A New Method of Manufacturing Gold Leaf

A London firm has introduced a novel, patented, process of making gold leaf even thinner than the best leaf produced in the usual way, although the new leaf really consists of three metallic films. A wheel of aluminium, some 5 ft. in diameter and $3\frac{1}{2}$ in. wide, has its periphery highly polished and then evenly coated with a soluble gummy material which, when nearly dry, receives a coating of very fine metallic powder. This metallic film is then polished and is electrolytically coated with a film of nickel by rotating the wheel with its lowest point making contact with the surface of a suitable solution of a salt of nickel containing the anode, while the rim of the wheel is the cathode. After washing, and again polishing if necessary, a film of gold is in the same way deposited on the nickel.

The composite film is removed by making one cut across its width, immersing the rim at this point in a liquid solvent of the adhesive substance and slowly rotating the wheel. As the film falls away a paper band, the motion of which synchronizes with the peripheral speed of the wheel, carries it off to be cut into slips and made up into books.

Engineering Imports and Exports.

The returns issued by the Board of Trade for the year 1912 show considerable increases in both imports and exports as compared with 1911, except imports of new ships. Iron and steel, including manufactures, were imported to the value of £12,070,862, an increase of £1,837,008; and were exported to the value of £4,862,918, an increase of £4,808,626. Imports in other metals, including manufactures, amounted to £31,100,808, an increase of £3,618,654; and exports reached £12,209,149, an increase of £1,276,613.

In electrical goods, the imports were £1,457,646, a rise of £22,154; and exports went to £6,369,877, or £1,550,503 more than for the previous year.

Imports of machinery are put at £6,820,744, an increase of £1,052,682; and the exports at £3,161,772, an increase of £2,201,104. The value of imports of new ships was only £33,654, showing a decrease of £30,830; but exports touched £7,031,809, an improvement of £1,368,784.

Taking the figures for December alone, imports of iron and steel increased £248,235 and exports rose £628,433; imports and exports of other metals went up £313,718 and £154,136 respectively; imports of electrical goods declined £1,117, but exports rose by £102,000; imports of machinery increased £160,001 and exports were £62,431 higher; new ships showed a drop of £500 in imports, but exports improved by £20,501.

Market Prices—January, 1913

Copper opened at £76-13 and declined slowly till the 8th (76) when it dropped sharply, reaching 75 on the 14th, and after short recovery to £71, 0/8 on the 20th. Improved to £71 on the 23rd, but again dropped, selling 69-0 on the 25th and closing 68-15.

Tin opened at £220.10 and showed only slight falling off to the 8th, then became more jerky and touched £227.15 on the 14th, and again declined sharply on the 18th, reaching £226 on the 21st. Has since risen, closing £230.

Cleveland opened 67/5, rose by the 7th to 68/- and has since been weak, being under 65/- on the 17th and down to 65/3 on the 24th. Since unsteady, but keeping near this price, it closes 65/3.

Hematite opened 82/- and remained firm till the 17th when it dropped away to 80/5, since recovering slightly to 81/-; closes 81/3.

Scotch Pig has been in sympathy with Cleveland, opening 74/- and dropping to 70/10 by the 17th. It closes a little better at 71/3.

Lead (English) opened £187.6 and has shown unusual variations. It was £18.18 on the 8th, and declined thence to £17 on the 12th, recovering to £17.10 by the 23rd, but afterwards weak; closing £16.17.6.

Recent Chemical and Metallurgical Patents

Gold and Silver

Sand-Slime Classifier.—The separate treatment of sand and slime products in cyanidation has created a demand for efficient means of separating these materials. A recently patented device for this purpose is shown in Figs. 1 and 2, being the invention of MR. PHILIP ARMIT, of Denver, Colo. The classifier consists of an inclined trough E, in which are placed two spiral conveyors I which rotate upwardly and inwardly. The trough may be divided into three portions, namely, B, in which settlement of sand occurs C where the sand is unwatered, and M, a filtering portion for withdrawing additional moisture from the sand. The inclination of the trough will vary from ten to twenty-five degrees, but for ordinary silicious ores probably will be about fifteen degrees. A weir G consists of a level strip over which water and slime may flow into a launder G. A feed-box is shown at A, provided with openings a', through which the mixture of sand and slime is introduced into the trough.

In operation the pulp is fed through the box A. The sand settles and is worked upwardly by the spiral conveyors, while the slime remains in suspension aided by the action of the conveyors, and overflows at G. The inventor states that he has devised the weir so that the overflow from a feed of six tons per hour will all pass a 150-mesh screen. The action of the conveyors results in building a bed of sand as shown in Fig. 2, and the slime and water draining from the sand bed finds its way into the side launders K' and runs back to the settling portion of the trough. The filtering portion consists

FIG. 1.—SAND-SLIME CLASSIFIER.

of angular slats L arranged transversely of the trough. If desired, a spray of water may be made to play on the sand as it passes over the filtering portion. In a modified form of classifier, the settling portion is circular, thus giving a larger weir. (1,044,844-5, Nov. 19, 1912.)

Slime Filter.—Various applications of a porous mineral septum in agitating and filtering mineral slime have been proposed by the advocates of the Just process, silica sponge being the material used. In patents recently granted to MR. W. W. RONAHER, of Rochester, N. Y., assigned to the Just Process Co., Syracuse, N. Y., it is proposed to use silica sponge brick as a facing on a revolving vacuum filter, as shown in Figs. 3 and 4 (p. 1001). The device consists of a drum 2 revolving in a tank 11 containing the slime to be filtered. The drum is covered on its sides with a porous mineral septum 6. The filter revolves on a hollow shaft actuated by gearing 12, 13. Vacuum is applied to the inner portion of the drum through pipe c, and causes a cake of slime to form on the faces of the drum, while cyanide solution is drawn through the septum and removed for precipitation. As the drum revolves and the cake is removed from the tank, it is removed from the filtering surface by means of scrapers 15 and transferred to a mixer 17, in which it is agitated with more solution or water and sent to a second similar filter. (1,051,160-1, Jan. 21, 1913.)

Copper, Lead and Zinc

Dry Chlorination of Mixed Sulphide Ores.—Among the recent efforts made to evolve a suitable process for treating complex sulphide ores, is one disclosed in a patent granted to MR. JOHN L. MAUM, of Denver, Colo. The principal steps

FIG. 2.—CROSS-SECTIONAL VIEW OF SAND-SLIME CLASSIFIER.

outlined in the present patent are the following. Fully crushed ore is fed into one end of a tube mill where it comes in contact with dry chlorine gas admitted into the tube from the opposite end. The reaction between the sulphides and chlorine evolves heat, but the temperature is controlled either by varying the quantities of ore and chlorine admitted, or by admitting the necessary quantity of air from the outside. In either case the temperature is maintained below the point at which sulphur monochloride or plastic sulphur would be formed as products of the reaction, thus preventing the ballooning or caking of the ore, and permitting every particle of it to be

acted upon by the chlorine. This step in the process affects only a partial chloridization of the ore, so that some of the metals exist as chlorides in the lower state of oxidation.

The ore is then transferred to an agitator, where it is treated with water or mill solution containing free chlorine, whereby the chloridization of the metals is completed and all exist as chlorides in the high state of oxidation. These chlorides are soluble and pass into solution, while the gangue and sulphur remain in a solid, granular state. The mixture is then filtered, and the metals precipitated from solution in any suitable manner.

It may be added that the procedure disclosed in this patent does not represent the finished state of Mr. Malm's process, other features being contained in pending applications. (1,049,746, Jan. 7, 1913.)

Hydrometallurgical Process for Copper Ores.—A process patented by Mr. JOSEPH IRVING, of Salt Lake City, Utah, has for its object the treatment of copper ores containing precious metals. It consists essentially of the following steps: Treating a low-grade carbonate ore of copper with dilute sulphuric acid solution, injecting steam and mechanically agitating the mixture, drawing off the resulting solution, passing it through a filter of sand and pyrites, and precipitating it on iron. The precipitated solution, containing at this time ferrous sulphate, is oxidized by agitation with air and injection of steam, and used for the treatment of a sulphide ore of copper containing the precious metals. Sodium chloride is added also, and the mass agitated mechanically and with steam. The resulting solution, containing copper, gold and silver, is then filtered and passed over iron and zinc to precipitate the contained copper and precious metals. On reoxidizing the precipitated solution and adding the requisite quantity of sulphuric acid, it is ready to be used on a fresh lot of ore with addition of salt. (1,048,541, Dec. 31, 1912.)

Pyrometallurgy of Zinc-Lead Sulphides.—A method for treating mixed zinc-lead sulphide ores has been patented by Mr. C. A. L. W. WITTER, of Hamburg, Germany. The ore is first finely ground and roasted until it is practically free from sulphur. It is then briquetted with a reducing agent and flux, as coal and lime, and fed into one end of a reverberatory furnace. The furnace is fired with gas, and in such a manner that the feed end contains a neutral or preferably re-

with lead fume by reason of the conditions maintained in the furnace. (1,047,360, Dec. 17, 1912.)

Nickel-Copper Mattes.—A process for the separation of copper and nickel in high-grade or concentrated mattes, patented by Messrs. ALEXANDER McKECHNIE, of Birmingham, and FREDERIC G. BEASLEY, of Smethwick, Birmingham, England, is claimed to be simple and effective. The raw or partly roasted matter is digested with sulphuric or hydrochloric acid at a

FIG. 4.—VACUUM SLIME FILTER

temperature of 100° C. in a closed air-tight vessel. Under these conditions of temperature and pressure the nickel is readily dissolved as nickel sulphate, when sulphuric acid is used, with evolution of hydrogen sulphide. The latter gas is utilized to the highest degree, under the conditions, for the precipitation of copper from solution as sulphide. Thus the single operation yields nickel in solution as sulphate and copper as a solid precipitate. Although the process can be applied to raw mattes, the inventors find that the action is accelerated by preliminary roasting. In the latter case, however, enough sulphide should be left to generate hydrogen sulphide for precipitation of copper. (1,047,825, Dec. 17, 1912.)

Rare Metals

Separating Uranium from Vanadium.—Solutions resulting from the treatment of carnotite contain both uranium and vanadium. The separation of these metals offers some obstacles, but may be accomplished readily according to a process patented by Mr. WARREN F. BLEECKER, of Canonsburg, Pa., and assigned by him to the Standard Chemical Co., of the same place.

The solution is first heated to about 90° C., and treated with heated sodium hydroxide in sufficient quantity to precipitate uranium as a mixture of sodium uranate and uranyl hydroxide. This precipitate carries some vanadium which must be separated by a further process. After filtering and washing the precipitate, it is dissolved in sulphuric acid. The solution is made slightly alkaline with sodium carbonate, and then electrolyzed with anodes of any desired metal, such as copper, nickel or iron. The vanadium will be precipitated as the vanadate of the anode metal, while the uranium will remain in solution and can be separated from the precipitate and converted into any desired form. (1,050,706, Jan. 21, 1913.)

Treatment of Radium-Bearing Ores.—A process supposed to be applicable to all known complex radium-bearing ores has been patented by Mr. SIDNEY RADCLIFF, of Bairnsdale, Victoria, Australia. It has for its object the separate recovery of the following products: (a) radium as radium and barium sulphates; (b) uranium as oxide or uranate; (c) acid earths such as tantalum, niobium, titanium, as oxides; and (d) rare earths such as cerium, thorium, lanthanum, didymium, etc., as oxides.

FIG. 3.—VACUUM SLIME FILTER

ducing atmosphere, while the opposite end is strongly oxidizing. The furnace contains a bath of slag on which the briquets fall. The metals in the briquets are reduced, the lead sinking through the slag bath, while the zinc vapor passes toward the opposite end of the furnace to the outlet. Here it is oxidized and subsequently caught as zinc oxide in flues and bags. The lead and slag may be tapped from the furnace periodically. The inventor claims that the zinc oxide will not be contaminated

The ore or concentrate is crushed to pass a 30 or 40-mesh screen. It is then fused in a reverberatory furnace with about $2\frac{1}{2}$ times its weight of acid sodium sulphate. When this charge has been fused, and while still fluid, sodium chloride to the extent of 10% to 15% of the weight of the ore is added and well rabbled. This causes complete decomposition and oxidation. The fused product is cooled and pulverized, after which it is agitated with warm water. Uranium, iron, the rare earths, and part of the acid earths will go into solution. Insoluble sulphates of radium, barium, lead and lime will remain in suspension. This turbid liquid is rapidly siphoned into a settler from which two products are obtained, namely, solution and fine slime.

The solution is treated with sodium carbonate, avoiding excess, which will precipitate iron, aluminium, chromium, uranium and the rare and acid earths. These are filtered from the solution and boiled with an excess of sodium carbonate which will cause the uranium to dissolve. The balance of the precipitate is treated with dilute sulphuric acid, whereupon all the slime except the acid earths will dissolve. These latter are filtered and ignited. The solution is treated with oxalic acid, which will precipitate the rare earths as oxalates, which are washed and ignited.

The fine slime contains most of the radium and is treated on the usual lines, and the crude radium and barium sulphates obtained in the usual way. (1,049,145, Dec. 31, 1912.)

Metallurgical Furnaces

Reverberatory for Copper Refining.—To prevent the disintegration and "floating up" of the bed of a reverberatory furnace, and to provide a furnace bed through which molten copper will not leak during the process of refining, are objects of improved furnace construction patented by Dr. J. B. F. HERRESHOFF, of New York City. In reverberatory furnaces hitherto used for copper refining the bed is composed of iron plates covered with fire brick on which is placed a covering of sand partly vitrified. A space beneath the plates constitutes a vault through which air may pass for the purpose of cooling the bed. It has been found that at times the molten copper will work its way down through this sand bed and cause the brick bottom to float, thus necessitating the temporary abandonment and repair of the furnace. The inventor has found that this disintegration of the bed is due to inefficient and imperfect cooling. As a consequence he proposes a construction whereby cooling may be accomplished uniformly, under suitable control, so that all parts of the bed may be kept cool enough to avoid the accumulation of molten copper below the brick bottom, and thus avoid disintegration and floating. In general, the invention may be said to consist of a series of pipes laid closely together in the bed of the furnace, both transversely and longitudinally, to carry air for the purpose of removing any desired amount of heat and thus keep the bed cool. Under this construction, any copper which may find its way through the bed will be cooled and solidified, and thus prevent further leakage. The heated air issuing from the cooling pipes may be used as preheated air at the combustion chamber of the furnace. (1,047,521, Dec. 17, 1912.)

Sintering Furnace.—In a patent issued to Mr. MILTON H. KAUFFMAN, of Denver, Colorado, the inventor describes the method of sintering or agglomerating fine mineral substances illustrated in Fig. 5. He makes use of removable pans 1 and 2, having perforated bottoms, which may be placed over an air box 6, which has a conduit 7 leading to an exhaust fan. His method of operation is to place a layer of material in the lower pan, with a layer of live coals in the upper pan, and set both over the air-box as shown. The exhaust fan draws air through the pans, as shown by the arrows, and ignites the layer of material in the lower pan. When ignition has proceeded far enough to continue without the aid of the live coals, the pans are removed and a third pan filled with mineral material is placed below the one previously ignited, and the pan containing burning fuel is removed. The exhaust continues to draw air through both pans with the result that ignition progresses from the upper pan to the lower, and the

material in the upper pan becomes completely sintered. The operation is then repeated, placing new material in a lower pan, while the partly sintered material is placed above, and the completely sintered material is discharged. (1,050,079, Jan. 7, 1913.)

Zinc Retort Furnace.—Novel construction for introducing gas and air into gas-fired furnaces, is the basis of a patent granted to Mr. ALEXANDRE FOLLIET, of Brussels, Belgium. In

FIG. 5.—SINTERING FURNACE

furnaces of the type mentioned, it is essential that the distribution of heat be uniform both vertically and horizontally, and the object of the present invention is to improve the manner of mixing the gas and air used in combustion. Accordingly, the gas and air are introduced through separate, narrow, adjacent slits, constructed and arranged to cause the air and gas to enter the combustion chamber in the form of thin, vertically-directed streams or "slices," parallel and adjacent to each other. These slices will thus travel side by side, so that the contact is progressive, permitting of the maximum development of flame and radiation of heat, since the broadest sides of the slices are in contact. No opportunity is afforded for the mixture of air and gas prior to their introduction into the combustion chamber, thus avoiding improper mixtures and consequent formation of darts of flame even when air is forced by a blower. Each group of slits consists of one gas port between two air ports; or five ports or any other odd number may be used, the only requirement being that each gas stream should issue between two air streams. These groups of ports are disposed at suitable intervals along each half of the furnace. (1,049,569-70, Jan. 7, 1913.)

Chemical Industry

Manufacture of Cyanide.—The synthesis of hydrogen cyanide was accomplished by Berthelot by electrically heating a mixture of nitrogen, gaseous hydrocarbon and hydrogen, the latter being present in such excess that the quantity of hydrocarbon present did not exceed 10%. In this process the output was small, and not commercially profitable. Recently IGNAZ MOSICKI and CASIMIR JABLONSKI, of Freiburg, Switzerland, have discovered that in the synthesis of hydrogen cyanide from the above constituents, the output increases with an increase of the percentage of nitrogen in the mixture, the proportion of hydrocarbon remaining the same. The dilution of the hydrocarbon with hydrogen, instead of with nitrogen, greatly reduces the output.

A specific example of the application of the improved process is given as follows: The basic substance is a gas made from oil having the following approximate composition: Methane, 50.3%; heavy hydrocarbons, such as acetylene, 22.5%; hydrogen,

23.2°C., and nitrogen, 4%. This gas is mixed with pure nitrogen and hydrogen so that the mixture will contain 74 parts nitrogen, 10 parts hydrocarbon and 16 parts hydrogen. The mixture is preheated and treated in an electric furnace having a revolving high-tension flame. In this a part of the gas is heated to a temperature between 2500 and 3500 degrees Centigrade, and the elements form hydrogen cyanide. That part of the gas which was not highly heated in the flame is not decomposed, and issues with the hydrogen cyanide, cooling the latter and preventing its decomposition. That part of the gas which did not enter into the reaction is now replenished with the necessary ingredients and again passed through the furnace. The hydrogen cyanide formed may be dissolved in caustic solution to form alkali cyanide. An intermediate reaction in the process causes some of the saturated hydrocarbons to change into unsaturated hydrocarbons, thus liberating a quantity of hydrogen which, if not removed, would accumulate to such an extent as to greatly reduce the output of hydrogen cyanide. This removal may be accomplished by any one of several methods, namely, by diffusion, by oxidation, by catalysis with air, as a result of which additional nitrogen will be added; by burning the hydrogen with a deficient quantity of oxygen, nitrogen being again added to the mixture; by oxidation with copper oxide at a low red heat. (1,050,078, Jan. 21, 1913.)

Manufacture of Phosphorus.—A process for producing phosphorus from mineral phosphates has been patented by Mr. FRANK S. WASHBURN, of Nashville, Tenn. The work of the inventor was based on the idea that a less volatile acid than phosphoric should displace the latter from its compounds, in a manner analogous to that in which sulphuric acid will displace hydrochloric and nitric from their compounds. After many experiments he found that it is necessary to mix a reducing agent with the phosphate and silica, and that the temperature of the electric furnace is required to cause the reaction to take place. When finely divided tricalcium phosphate, silica and carbon are subjected to the temperature of the electric furnace, the phosphorus is driven off rapidly and up to 90% of the whole. Sufficient air is brought in contact with the evolved phosphorus to form the pentoxide, which may be absorbed in any desired medium. (1,047,864, Dec. 17, 1912.)

Electric Storage Batteries

Preparation of Films or Flakes of Nickel.—In storage batteries of the Edison type, films or flakes of metallic nickel are used in the makeup of the positive electrodes. Mr. THOMAS A. EDISON, of Llewellyn Park, West Orange, New Jersey, has patented a method for producing these films, consisting in first making composite sheets of alternating thin layers of copper and nickel electrolytically deposited, cutting these sheets into strips and flakes of suitable size, and then dissolving the copper with a suitable solvent which will not affect the nickel. Such solvents patented by Mr. Edison are (1) a 25% solution of copper sulphate containing about 15 grams cupric chloride per liter. Other reducible haloids may be substituted for cupric chloride but they are not as desirable. (2) a solution containing 285 grams ammonium sulphate and 10 grams cupric chloride per liter. When the metallic films of copper and nickel are agitated with these solutions, preferably warm, the copper separates as basic sulphate and may be decanted with the solution, leaving the nickel flakes to be suitably washed. This process is preferable to a former method of Mr. Edison's, in which he used an ammoniacal solution of copper sulphate, with attendant loss of ammonia, and the difficulty of recovering the copper in a desirable condition. (1,050,629-30, Jan. 14, 1913.)

Gage numbers of wire have no significance unless the gage is named. Thus No. 5 gage varies in diameter from 0.181 to 0.220 in. in six different standard gages. A far better way of specifying sizes of wire is to give diameter in decimals of an inch. This method is accurate and eliminate possibilities of error in filling orders.

Synopsis of Recent Chemical and Metallurgical Literature

Gold and Silver

Air-Lifts vs. Centrifugal Pumps.—At the all-sliming cyanide mill of the Cia. Minera Jesus Maria y Anexas, San Jose de Gracia, Sinaloa, Mexico, centrifugal pumps were used to elevate the mill discharge and the final slime product. In the *Colorado School of Mines Magazine*, January, 1913, Mr. W. B. RHOODES describes the troubles encountered with the pumps, and their replacement with air-lifts. The pumps wore badly and gave constant trouble and expense. Of the two air-lifts installed, one had a 2½-in. lift pipe, with 65 per cent submergence, giving an effective lift of 18 ft. The other had a 3½-in. pipe, 54 per cent submergence and 38-ft. lift. The former was used for the sandy tube mill discharge and the latter for slime. The sand lift has plugged at times, but by the use of high-pressure air it has been cleaned without serious difficulty. Air is used at a pressure of 25 lb. per square inch. The total cost of the air-lifts, including the sinking of a shaft, 5 ft. square by 40 ft. in depth, was only \$300. The cost of installing an old compressor was \$150. The saving which has been effected by the air-lifts is as follows:

Maintenance of centrifugal pumps, including cost of pumps, liners, shafts and mechanics' wages, per month	\$200.00
Saving of 20 per cent in horsepower, or 5 hp at \$1.25 per day, 30 days.....	187.50
Saving 12 hours per month, equivalent to 40 tons ore at \$25 per ton.....	1,000.00
Total monthly saving.....	\$1,387.50
Total annual saving	\$16,650.00

These two lifts have been working steadily for two years without interruption and have saved approximately \$30,000. The air consumption varies from 2½ to 3 cu. ft. for each cubic foot of sand or slime lifted, depending on the dilution of the pulp. For the slime lift of 38 ft. a minimum dilution of 5:1 was found necessary to give good results. The sand is lifted at a dilution of 3:1.

Cyaniding at the San Poil Mill, Republic, Washington.—Preliminary cyanide tests on the ore of the San Poil mine indicated possible extraction as high as 98 per cent when the ore was crushed to 200-mesh and treated with a 5-lb. cyanide solution. The strong solution was required on account of the silver in the ore. Mr. EDWARD C. MORSE describes the operation of the mill in the January, 1913, *Bulletin of the Amer. Inst. Min. Eng.* One of the interesting features of the work is the use of a Williams hammer pulverizer for crushing the ore to 3/16 or 1/4-in. size. This machine receives the run-of-mine ore. It is similar in operation to the Quenner dry-placer machine used in Mexico for breaking cement-gravel; it has been used by the government for making sand for concrete purposes at the Cello locks on the Columbia River. Its use in the San Poil mill is its first application to ore crushing.

The Williams hammer pulverizer consists of a central shaft carrying thirty-two 16-lb. hammers suspended by chains. The shaft revolves at 600 r.p.m. within a trommel built of grizzly bars 2 in. deep, with a 1-in. face, spaced 3/16 in. apart. The machine has shown a capacity of 15 tons per hour of run-of-mine ore. Sizing tests of the product have shown as high as 40 per cent passing 20-mesh, of which 65 per cent was finer than 10-mesh and 6 per cent as fine as 200-mesh. When the ore fed is wet the machine does about twice as much fine crushing as with dry material, but has lower capacity.

The crushed ore is sampled and run through a set of finishing rolls provided with carborundum blocks to prevent grooving of the rolls. The product is as fine as 8 or 10-mesh, and is sent to a tube mill, the discharge of which is classified by a Dorr classifier, and the sand returned for further grinding. The slime is thickened and agitated in a series of nine air lift agitators, 12 ft. diameter by 18 ft. high. The tanks are connected in series, and the material passes from one to the

2 Pumps	16	16	32	32
1 14-in. conveyor	4	2.5	16	2.5
Total electric power				214.5

The average cost of steam power is 2 cents per hp-hour, and of electric power $1\frac{1}{2}$ cents per hp-hour. The mill is treating well over 3000 tons of crude ore per week of 144 hours.

Some points of interest in the mill are the following: All Wilfley tables are fitted with riffles ending in a special curve at the delivery end, determined by experiment, to separate the fine lead from the rhodonite. All launders are of $\frac{1}{4}$ -in. steel, parabolic in section. A 3-in. centrifugal pump with flooded suction and 2-in. delivery pipe, gives satisfaction in raising lead

concentrates at the rate of 1000 lb. per hour. The draining belt used to carry tailings from the mill is 24 in. wide and 50 ft. long. The first 20-ft. section is in the form of a semi-circular trough, with slight slope so that water will drain back. The belt then rises sharply at an angle of about 15 deg., and this, with the addition of a bumper, dewater the tailings sufficiently for use in underground filling. The moisture can thus be reduced to 5 per cent.

A minerals separation plant is now being erected to treat the ore after the jig lead has been extracted. The mill circuit will be broken at the table screens in both quartz and rhodonite sections, and from these all the undersize will run to the flotation plant. Old dump material also will be treated by flotation.

Chemical Analysis and Assaying

Variations in Assaying Gold Ore.—Tests were made at the Akaska-Treadwell mine to determine the error in assaying gold ores, and the degree of accuracy which would be considered satisfactory for mill-feed, concentrate and tailing. Mr. W. P. LASS gives the details of the experiment in the *Mining Magazine* for January, 1913. To summarize the results, the average variation of one assay from another on mine and mill samples, averaging \$3.46 per ton, was 41.3 per cent. The average variation on tailing samples, averaging 32.7 cents per ton, was 20.6 per cent. The average variation on concentrate samples, averaging \$68.79 per ton, was 7.6 per cent.

The author accounts for these variations by the fact that the gold occurs in Treadwell ores in free gold particles. There are at least 280,000 particles in one assay-ton of 40-mesh sand. If one of these particles be fine gold it would increase the gold content of the ore \$21.52 per ton. In one assay-ton of cubic particles of the same dimensions as the openings in a 100-mesh screen there are at least 5,348,811 particles; if one of them be fine gold it would increase the assay result \$1.12 per ton.

In ten different samples of concentrates the average first assay was \$68.81; the average second assay was \$68.77; the average variation was \$5.21, or 7.6 per cent figured on the average of twenty assays and the average variation. Twenty-eight mine and mill samples gave an average first assay of \$3.50; average second assay \$3.41; average variation, \$1.43, or 41.3 per cent figured on the average of fifty-six assays and the average variation. A point of particular interest is that though the average variation may be great, the average value of the samples remains approximately the same. It is a compensating variation. In ten tailing samples the average first assay was 32.5 cents per ton; the average second assay, 32.9 cents; the average variation being 6.7 cents, or 20.6 per cent figured on the average of the twenty assays and the average variation.

Assay of Cyanide Solutions.—The different schemes proposed for the assay of gold-bearing cyanide solutions are reviewed by Mr. L. J. WILMOTH in the February, 1913, *Merican Mining Journal*. The following diagram shows the classification of the different methods:

Of the evaporation methods, it is the opinion of the author that the first is antiquated and no longer in use; the second is seldom used, and is inferior to the third, which he regards as undoubtedly the best, but undesirable on account of the time needed.

Of electrolytic precipitation methods, there are those in which the gold is deposited by means of an extraneous current, and those in which the gold is deposited by means of an electric couple formed by two metals brought into the solution to be assayed. The first method is unimportant and has never been brought into commercial use. The second class of methods includes several which are of interest and importance. In

all these methods a given quantity of cyanide solution is acidified with sulphuric or hydrochloric acid; a solution of copper sulphate or lead acetate is then added, and the gold precipitated by introducing metallic zinc or aluminium to form the electric couple. Arant uses sulphuric acid, copper sulphate and aluminium. Chiddy's method requires hydrochloric acid, lead acetate and zinc shavings; and Holt proposes the use of hydrochloric acid, lead acetate and aluminium. The author believes the method of Chiddy to be the best; it is most extensively used. The use of copper solution is undesirable on account of the difficulty of eliminating the copper in the assay. Zinc is preferable to aluminium as it passes into solution more readily, is cheaper, more easily procured and just as effective.

In the second division of precipitation methods we find those of Crosse and Whitby. The former uses an excess of silver nitrate to precipitate a double gold-silver cyanide, while the latter relies on an acidulated solution of copper sulphate to throw down a double gold-copper cyanide. Crosse's method is regarded as costly, and has been superseded by others. Whitby's method is regarded as being in the same class with Chiddy's and the evaporation with litharge is being most extensively used.

The calorimetric methods have not been widely adopted. They all depend on the precipitation of gold from solution, redissolving it and then adding stannous chloride to form purple of Cassius. Moir first destroys the cyanide by addition of sodium peroxide. A few drops of lead acetate solution is added and a very small quantity of aluminium stirred in. This is not unlike Holt's electrolytic method. Prister precipitates the gold with a solution of copper sulphate and an alkaline sulphide, while Cassel uses potassium bromide and sulphuric acid.

Of all the methods proposed there are only three that are widely used. The evaporation method may be said to be in universal use; in America Chiddy's method is widely adopted, while Whitby's method is used in most of the mines of South Africa.

Assay of Zinc-Dust Precipitate.—In a paper presented before the American Metallurgical Society in June, 1912, Mr. H. R. LAYNG gives his procedure in the assay of zinc precipitate. The sample is ground on a bucking board to pass a 60-mesh screen. It is then thoroughly mixed and finally spread to a uniform depth of about $\frac{1}{2}$ in. By the use of a square-end spatula a sample is taken by dipping from various parts of the layer of dust. This is dried, cooled, and then mixed and spread again. Three samples of 0.1 A.T. each are then dipped by means of a spatula $1/16$ in. wide. Each sample is placed in a 10-gm. Battersea crucible, previously dried and containing 10 gm. test lead and $1\frac{1}{2}$ gm. of a mixture composed of one part each of potassium carbonate and sodium bicarbonate and two parts horax glass. The precipitate is mixed with this charge and the crucible is tapped to settle the mixture evenly.

Three fluxes are used in assaying the original charge, the resulting slag and the cupels. They are shown below:

	No. 1.	No. 2.	No. 3.
	gm.	gm.	gm.
Sodium bicarbonate	400	600	1 part
Potassium carbonate	400		60 gm.
Litharge	800	1200	$5\frac{1}{2}$ parts
Silica	250	200	$8\frac{1}{2}$ gm.
Charcoal	30	$12\frac{1}{2}$	1 gm.
Borax glass			3 gm.

After mixing the sample with lead as described above, 20 gm. of flux No. 1 is added, allowing it to wash around the sides of the crucible. This is leveled and covered with 20 gm. of flux No. 2. The general effect of these fluxes is to catch any gold or silver which might be carried to the top of the crucible. It will be noted that the charge is of such a character that lead is reduced in successive stages, and not all at once as in the ordinary assay. The crucibles are subject to low red heat until fused, then finished at a higher temperature for 10 minutes, and poured.

The buttons are cupelled carefully. The slag is assayed in the original crucibles, using 20 gm. of flux No. 2 and 10 gm. charcoal. The button resulting is cupelled separately, and the weight added to that of the original.

The cupels are assayed for absorption loss by grinding to 150-mesh, and assaying 10 gm. with 70 gm. of flux No. 3, together with 1 gm. charcoal and a borax cover. The author finds that his method gives higher results than other fusion methods, and compares favorably with the volumetric methods for silver. Assays check within 5 or 10 oz. on precipitate carrying 20,000 to 22,000 oz. silver.

Electrolysis

Chlorination of Benzene by Electrolysis.—A paper by R. G. Van Name and Carlton H. Maryott, in the February, 1913, issue of the *American Journal of Science* discusses the mechanism of the chlorination of benzene in the electrolytic cell. The investigation was carried out in the Kent Chemical Laboratory of Yale University. The chief results are as follows: (1) Electrolysis of benzene in a solution of lithium chloride in glacial acetic acid gave chlorinated benzenes with current yields, under favorable conditions, of 50 to 70 per cent. Both addition and substitution chlorine were present in the product, the latter predominating. There was, however, nothing to show that the effects were not due to the secondary action of chlorine previously set free by the current and dissolved in the liquid.

(2) Benzene dissolved in the same solution is really chlorinated by direct treatment with chlorine gas in the dark, yielding addition and substitution compounds in proportions which vary with the conditions.

(3) The addition of benzene to the acetic acid-lithium chloride solution during electrolysis raised the anode potential, and by an amount equal to or greater than that produced by a similar amount of carbon tetrachloride. This indicates that benzene has little or no depolarizing power toward chlorine, at least in this case. Phenol, added under similar conditions, produced a decided lowering of the anode potential.

(4) The rate of chlorination of benzene, when dissolved in the same medium saturated with chlorine, was measured at 10.2 deg. Simultaneous electrolysis did not accelerate the chlorination perceptibly under conditions where a 10 per cent current yield should have been evident. The current yield, if appreciable, was therefore below 10 per cent.

(5) The products of 4 contained addition and substitution chlorine in the ratio of about 2 to 3, this ratio increasing slowly as the reaction progressed. The reaction velocity, calculated on the assumption that monochlorobenzene and benzene hexachloride were the sole products, showed a steady rise, but the rate of chlorination of monochlorobenzene, separately determined, appeared to be sufficient to account for this effect.

(6) No positive evidence of strictly electrolytic (i. e., anodic) chlorination of benzene was obtained.

Non-spinning wire rope, the invention of Olof Tangring, an engineer of the American Steel & Wire Company, is made by first winding one series of wire strands over a core in one direction, and an outer series over the inner series as a core in the opposite direction. The wires composing the inner strands are twisted in the same direction with them, but in the outer strands the wires are laid in the opposite direction to them. The construction results in the counteraction of the tendency of the rope to spin when used in hoisting or lowering loads.

The melting point of cupric oxide has been investigated by R. E. Slade and F. D. Farrow (*Zeit. Electrochem.*, XVIII, 817), who find that the pure salt does not melt below 1148 deg. C. Decomposition occurs at this temperature, even with a pressure of 2.5 atmospheres, producing cuprous oxide which forms a solution with the cupric oxide solidifying at about 1081 deg. C. Under a pressure of one atmosphere the decomposition begins at 1000 deg. C., and the solution, containing over 50 per cent cuprous oxide, solidifies at about 1064 deg. C., which is the value given by Wöhler for the true melting point of copper oxide.

Chemistry in Russia in 1912

Russia as a chemical producer is a comparatively new comer. But there are some branches of the industry which have acquired what the Russian calls "citizen rights" in the country and which have developed in a very satisfactory manner. These are particularly soda and acids.

As far as the year 1912 is concerned the year has been a very satisfactory one, although more from the importers' point of view even than from the manufacturers'. The Russian field for foreign chemical products is an immense and a growing one, and will be worth more attention for many years to come, because the industry, as suggested above, is only partially developed in the country. Anyway during the year under review the factories were kept working all the time, and some of them were at times in straits to comply with the orders they received.

The market value of chemicals in the country did not vary very much last year, but there are some leading items that suffered changes in price, such as sulphuric and nitric acids, borax, prussiate of potash, and the like. Prussiates rose rather briskly, because of the stocks becoming exhausted both in Russia and Germany. There was also a substantial advance in lead, zinc, and copper compounds on account of the increase in the value of the respective metals, and the advance was maintained right to the end of the year, or nearly so. But the important Russian chemical products, as stated, are sodas and the value thereof had slightly declined in comparison with 1911 both for calcined and caustic. But it is objected and regretted that these particular goods should be so high in prices when they enter so largely into the economic life of the country. For example, the average cost of calcined soda last year was 1 rouble 16 copecks per pood; and the average cost of caustic soda was 2r. 47c. per pood.

Chemicals as a rule are protected by a tariff, and it is only when an agitation grows pretty strong that the quasi monopolists consent to make a slight reduction in order to avoid further attention being called to the fine business they are doing. But perhaps the most interesting development in the Russian chemical industry is the most recent one, namely, the alacrity with which the South Russian metallurgical works are adopting by-product coke ovens; the most interesting for the moment among the by-products is ammonia, because the Russian agriculturist is becoming a larger consumer every year of fertilizers—both home-made and imported.

But although this business has been catered to generously in the South, the first cost of the soda appears to the agriculturist to be so high as to discourage him from adopting it on a large scale; and the consequence has been that the production of sulphate of ammonia has not made the progress that was expected of it. It will be some time evidently before the Russian farmer will learn to appreciate the value of ammonium sulphate as a fertilizer. On the other hand, he is becoming a very large consumer of superphosphates. These were imported last year in far greater quantities than ever before—in fact, the imports increased at a much greater rate than the production at home, which is not unimportant. It is not that phosphate rock does not abound in Russia that causes him to buy the superphosphate abroad. Phosphate rock is plentiful enough in the country, but the difficulty is to get sulphuric acid cheap enough and the phosphate rock is not found in comfortable proximity to either native sulphur, of which there is a very little in the country, or pyrites.

In the Ural region there are large deposits of phosphate rock close enough to the pyrites, but unfortunately these particular deposits are poor and it becomes a question whether it will pay to work them even with convenient supply of acid. On the other hand, the Zerkovo (that is, district council) of Perm has decided to erect a superphosphate factory at public cost in order to supply the agricultural needs of the Perm and Viatka governments. The richest phosphate rock deposits in Russia are in the Southwest (Podolia) and they are largely exported into Austria unmanufactured. There does not ap-

pear to be sufficient enterprise amongst the industrial chemists of Russia to turn these deposits to account. The trouble is always, they will tell you, the question of acid.

The importation of fertilizers into Russia in 1912 during the first 10 months amounted to close on 24,000,000 poods, which compares with a little over 19,000,000p. in 1911 and close on 10,000,000p. in 1910, always during the first ten months.

It is hoped that in the course of time Russian industrial chemistry will be able to deal with the other byproducts of the coke oven, such as benzol and so on, for the purpose of establishing an independent color industry, but that time is probably still far off.

Besides superphosphates, the Russian farmer consumes large quantities of Chile saltpetre and German potash salts, both of which were imported last year in larger quantities than in any preceding year.

While Russia manufactures largely for her own use under the protection of a high tariff wall in several branches of chemistry, she can hardly be said to have an export trade in any of them, an exception being the products of wood distillation. This industry in Russia has entered into a very interesting phase. For many years back Russia has exported a turpentine of deplorably inferior quality which only gets a chance, say, on the English market when American turpentine becomes very high in price. A large customer for it is Germany where it is hardly ever turned to any account, however, until it has passed through the refineries there. But it is used in other countries, and perhaps in Germany, too, for mixing; but probably not to any large extent.

During the last year or two systematic experiments have been made for distilling the resin and it is claimed that this has been accomplished with great success, the prospect held in view being that in a very few years French, and particularly American, turpentine will have lost their significance for the Russian market; because the Russians have the raw material in abundance, there will be no difficulty in supplying their own needs independent of supplies from either America or France to which countries they have had to look in the past for turpentine of anything like quality. This applies also to rosin.

There is a point, however, that has to be considered in connection with this feature of Russian chemistry, namely, the question whether the Russian climate will be favorable to tapping the trees, as is done in France. Should it prove that the severity at times of the Russian weather does not discourage this preliminary operation in connection with the production of turpentine and rosin, it is quite likely that American and French goods under these headings will soon cease to be quoted on the Russian market.

As hinted in the first few lines although Russia has made enormous strides in the manufacture of a limited number of chemicals, if we take the whole field she is still so far behind in the race that chemical manufacturers in other countries may well cultivate the market in full confidence that it will be available for their goods for many years to come. Germany knows this and is doing an immense business with her neighbor over the border, not only in colors, in respect to which, of course, she leads the world, but also in other chemicals when other countries may easily become serious competitors.

St. Petersburg, Russia.

Six Chapman Rotary Gas Producers, built by the Chapman Engineering Company, of Mount Vernon, Ohio, are being installed at the open-hearth plant of the Bethlehem Steel Company at South Bethlehem, Pa. Three Chapman gas producers of the same type have been ordered by the Tremont Nail Company for its open hearth at West Wareham, Mass., and one by the Crucible Steel Company, of America for its plant at Syracuse, N. Y.

The consulting engineering firm of Mr. E. S. Lincoln, of Waltham, Mass., has been incorporated as E. S. Lincoln, Inc., and has moved its offices to the new laboratory now nearing completion at 129 Bacon Street, Waltham.

The Apophorometer

A paper by Prof. J. Joly in *Philosophical Magazine*, February, 1913, describes the "apophorometer" which is an instrument for enabling sublimates obtained from substances at high temperatures to be collected in their entirety and weighed on the chemical balance for purposes of chemical analysis, identification or research.

The apophorometer is a very simple instrument. A ribbon of this platinum, about 6 cm. in length and 4 or 5 mm. in width is stretched between two forceps which are provided with binding-screws so that a current can be sent through the ribbon, raising its temperature to any desired degree up to the melting point of platinum. One of the forceps is movable parallel to itself, and is so acted on by a light spring that the ribbon is kept stretched. The substance to be volatilized is placed in the form of powder upon the ribbon or hob. Beneath the ribbon a watch-glass is held in position by a support which can be raised or lowered or rotated to one side. When this watch-glass is in contact with the ribbon a second watch-glass is placed on the lower one. The ribbon is thus enclosed between the glasses for nearly its entire length. Overall a receiver fits enabling

APOPHOROMETER

an indifferent gas to be introduced around the heated substance or a vacuum to be established.

The procedure is as follows: The lower watch-glass is raised till it is in contact with the ribbon. From 5 to 30 milligrams of the substance are distributed over the ribbon so as to extend nearly over its entire length. The upper glass is then laid on. All is now ready for the experiment. In some cases it is desirable to weigh the platinum ribbon before placing it in position. And again in some cases it is advisable to make a preliminary experiment on a portion (not weighed) of the powder in order to observe the behavior of the substance.

A current is now passed through the ribbon and gradually increased. It may be that more than one sublimate is obtainable from the substance by careful regulation of the temperature; or it may be that only the one is to be expected, and the residue being non-volatile very great care in raising the temperature is unnecessary. When the sublimate is coming off freely the high temperature is maintained unaltered for from 10 to 15 minutes or until the sublimation is seen to be completed. The current is then cut off and the glasses let cool; but while still considerably above air temperature the upper glass is lifted off, the lower one let down and removed, and both glasses are clipped together for weighing. This is important, as some sublimates are hygroscopic. It is well to use watch-glasses which are ground to meet accurately.

It has been assumed that the presence of oxygen is not injurious. In many cases it is not. If it is, the receiver must be taken into use and the air excluded.

If there is any uncertainty as to the completion of the process, a second pair of watch-glasses should be placed around the ribbon and the current again turned on. We can thus make sure that the volatile constituent has been completely removed.

The whole process is one of ease and simplicity. It enables the nature of the sublimate to be anticipated, and its character enables it to be determined, and of course analytical tests may be applied to it after its weight has been ascertained. Knowing the nature of the sublimate the amount of oxygen may be calculated out.

The weight of residue left upon the ribbon is of no instances of importance. But it is necessary to bear in mind that the residual element may be oxidized in these cases. A re-excess of oxygen has been permitted. It will sometimes be found that from this cause the residue may actually weigh more than the original sample of the substance.

Certain substances may alloy with the platinum, and owing to the extreme thinness of these wide ribbons, cause it to fuse. These may be dealt with either on heavier platinum ribbon or on carbon. Molded strips of carbon would, doubtless, be obtainable. In point of temperature-range carbon has also advantages, but this is of minor importance, for there are few sublimates not obtainable by the use of platinum. It should be remembered that ordinary carbon may contain volatile impurities. If we desire to deal with very high temperatures the watch-glasses should be of transparent vitreous silica. The results obtained by this method with various substances are described.

The Non-Ferrous Metal Market

In general the tone of the non-ferrous metal market is weaker than reported a month ago. In view of the unsettled conditions, buyers are not anxious to enter the market, and as a consequence concessions have been made by the sellers. Special brands have commanded special prices, but ordinary requirements have been met at lower figures.

Copper.—Concessions have been made to induce buyers to purchase, and the market has fallen to a point that makes buying attractive. Few transactions are reported in Lake copper, and the quotations are nominal. The latest quotations are for Lake, 158¢ to 158½¢ cents; and for electrolytic, 152½¢ to 153¢ cents.

Tin.—The market is generally low in view of the decline in London. Domestic purchasers have entered the market freely and the metal is again becoming scarce. February tin in the domestic market is quoted at about 40½¢ cents.

Lead.—This market is quiet, and prices have not changed materially. The foreign market is slightly firmer. The latest quotations are 4.15 to 4.20 cents, St. Louis, and 4.30 to 4.35 cents, New York.

Spelter.—This market is weak with a slight decline. The price has declined twice during the month and at last reports was 5.05 to 5.15 cents, St. Louis, and 5.20 to 5.30 cents, New York.

Other Metals.—The aluminum market has been rather dull, with metal selling at 23½¢ to 24¢ cents, New York. Prices for antimony also have declined slightly, different brands bringing from 8.25 to 9.00 cents per lb. The quicksilver market is quiet but prices are unchanged at \$40 for domestic orders and \$37.50 for export.

Portland cement manufactured in the United States in 1912 is estimated by the U. S. Geological Survey at 8,049,088 barrels, which estimate is believed to be correct within 1.3 per cent. The production showed an increase of 4.3 per cent over that of 1911. The curve of production of Portland cement is still rising and has yet to take its last downward turn.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines of November, 1912, was 62. The total quantity of ore milled during that period was 2,213,000 tons. There were 9000 stamps in operation with an average duty of 8.58 tons per 24 hours. The mills in commission numbered 280. The yield for the month was 757.33 fine ounces gold. The report shows a steadily decreasing number of stamps and increasing number of fine mills in use.

Standard Screens for Screen Analyses

By Robert H. Richards

Great interest has been shown in recent years, and rightly so, in the importance of having standard sizes of screens, or sieves, in laboratories where sampling and screen-sizing has to be done. The need of such a standard is occasioned by the fact that without it the worker on mill or furnace products in one part of the country can not read the article written by the worker in another part of the country, and translate the figures obtained into the measures that he is used to in making his own experiments, unless he knows the sizes of grain that are dealt with in the experiments described.

Some efforts have been made in this direction up to the present time, and the writer will refer to two. The sieve scale adopted by Rittinger, in his work on ore dressing, started with 1 mm. and laid out the different sizes for the screen holes, for sizes above 1 mm., by multiplying each lower size by 1.414, or the square root of 2, in order to obtain the size next larger; going up in this way until he reached the largest size that in all probability would be needed, namely 64 mm., which is about $2\frac{1}{2}$ in. in size, and going down to sizes below 1 mm., by dividing the size of the hole in each screen by 1.414, in order to obtain the size of the hole in the screen next smaller, and so on down the series until the smallest possible size of screen hole was reached. In bringing out this sieve scale so far as we know Rittinger simply worked it out as a very desirable plan, but so far as we know no manufacturer took up the making of the screens, and no standard set of screens were to be had.

The second instance to which the writer will refer is the standard set of sizing screens adopted by a commission appointed by the Institution of Mining and Metallurgy of London, and presented at their twentieth session 1910-11. This commission took the ground that miners, mill men, and metallurgists are so wedded to the use of the word "mesh" as description of the size of a sieve that it was unwise to try to introduce any other mode of designation except "mesh."

It is known to all who have given any thought at all to the matter that the word "mesh" does not define the size of the sieve hole, and therefore the size of the product which the sieve makes; for example, the writer has before him the catalog of a manufacturer of screens, and in it he sees that a 14-mesh screen, with the coarsest wire that is ever used by this company would have a hole 0.030 of an inch in diameter, while the 14-mesh screen, with the finest wire that is ever put into that size of screen would have a hole 0.061 of an inch in diameter; and there are sieves made by this manufacturer that have fourteen different sizes of wire, ranging between the above two extremes; 14-mesh sieve therefore has sixteen different sizes of hole according to the sixteen different sizes of wire used. Therefore the writer who speaks of a 14-mesh sieve in his descriptive article may mean to his reader that he is talking about grains anywhere from 0.030 of an inch to 0.061 of an inch, failing utterly to convey a scientific fact to his reader.

The commission, aforesaid, in making their screen set, known as the I. M. M. standard screens, fully realized this difficulty, and met it by arranging to use wires of the same diameter as the width of the holes. This gives the reader definite information as to the size of the grain that is meant when a particular mesh of the sieve is used. These screens, however, do not have a constant ratio between two adjacent sizes; in fact the ratio between the width of 100-mesh holes and 90-mesh holes is 1.095, while the ratio between 30-mesh and 20-mesh is 1.508. Other lesser variations occur all the way along the series, and in fact there is no attempt at a uniform ratio.

There is another difficulty which this method runs against, and that is, that in order to have screens of uniform size of opening, we must use double-crip wire cloth, and a prominent manufacturer of screens informs the writer that it is quite difficult to make double-crip wire cloth where the wire is as

large as the size of the holes, particularly when one gets to the coarser sizes, and if single-crip wire cloth is used, the wires are not fixed, and the sizes of holes will vary to a ruinous extent by the slipping of the wires.

In regard to the use of a constant ratio between the sizes of holes of the adjacent sieves, the writer believes there are very strong reasons in favor of using a constant ratio. If one is making a series of sizing tests from a crushing machine, one wishes to know the proportional amount of the sizes at different points down the series, and will probably wish to draw a curve of the same. If one pair of sieves has a very small ratio of sizes of holes, and another has a very large ratio, then no regular statement of quantities of products made by the oversize of the successive sieves will give its full meaning, nor will it be possible to make a curve which will truly represent the result of that crushing operation.

Also if the series of products obtained are to be subjected to any concentrating operation, with a view to ascertain the ability of the ore to be concentrated, there will be no fair comparison between two products, using the above illustration, where in one instance the coarsest grain in the product is 1.5 times the size of the finest, while in the second case the coarsest grain in the product is only 1.09 times the size of the finest grain in the product. The work of concentrating on two products differing so completely in their limits of size as those two products would differ, would fail entirely of being comparable one with the other.

Again, the very fact of using "mesh" as the standard of size of sieve invites the man who has not obtained the I. M. M. standard sieve to talk about his products by use of the word "mesh," when his products are made by sieves of different make, and therefore have different sizes of holes from the I. M. M. standard screens.

On these three accounts (1) the difficulty of making double-crip wire cloth of such coarse wire; (2) the difficulty of drawing deductions from curves, and of comparing results; and (3) the difficulty of having others not provided with the I. M. M. standard entering into the discussion and using the word "mesh," it seems to me that a standard set of screens, which is standardized according to the size of its hole, instead of according to the number of meshes, and that has a constant ratio from one end to the other, for example, Rittinger's ratio of 1.414 or the square root of 2, and having the liberty to use wires that are smaller than the size of the hole, admitting therefore of the use of the most perfect kind of double-crip wire cloth, can not fail to have great advantages over the series of standard screens based upon mesh.

Such a set of standard screens has just now been prepared by the W. S. Tyler Company of Cleveland. This set of screens begins with 200 mesh as its starting point, which is a size of screen that has been standardized at Washington by the U. S. Government, and uses the ratio upwards from that point of 1.414, running all the way to the maximum size. These screens are made with the greatest care in order that they shall always be standard in size of hole, and in order that the various experimenters in the different parts of the country who make screen analyses of their products can read each other's results, and know exactly what is meant by the results.

Since the ratio between the width of the hole between the next small screen and the next larger is always the same, namely, 1.414, a sizing test made by this set of screens will give the proportional quantity of material that belongs between each two sieves according to a perfectly definite law, that is to say the largest grain in any product will always be 1.414 times the size of the smallest grain in that product. As a consequence of this the series of products obtained will have their quantities, or weights, proportional to a perfectly definite law, with the variable ratio entirely eliminated. They will yield curves which truly represent those quantities according to that definite law, and if concentrating tests are desired upon these products, the results of concentrating will be comparable all the way down the line of products, ranging from the coarsest to the finest.

The writer warmly commends this effort to make a valuable standard set of screens for use in screen-sizing tests, and hopes that they will generally be adopted by the mining engineers, the mill men, and the metallurgists of the country, in order that the papers written on these various subjects may have the greatest uniformity in the description of the products entering into such discussions.

*Massachusetts Institute of Technology,
Boston, Mass.*

An American Oil Engine Test

The Busch-Sulzer Bros.-Diesel Engine Company of St. Louis, Mo., have just issued a well illustrated booklet, entitled "The Diesel Engine—A Test," which seems to deserve some comment.

The booklet gives the report of an exhaustive test of a 225-hp, 4-stroke cycle, Busch-Sulzer-Diesel heavy oil engine. This is the engine invented by Dr. Rudolf Diesel, of Munich, Germany, and introduced into the United States under patents and licenses obtained from Dr. Diesel by Mr. Adolphus Busch, of St. Louis, and built by the Busch-Sulzer Bros.-Diesel Engine Company, of St. Louis, in the shops of the Power & Mining Machinery Company, Cudahy, Wis., and installed a little more than a year ago in the plant of the Hugo (Okla.) Ice & Light Company.

Since most that has been written in this country about performances of the Diesel engine has been based upon the showing of European tests, the results of this American test of an American built Diesel heavy oil engine, designed on lines to meet the best ideals of American practice, are interesting.

The test was made on the 225-hp Diesel engine mentioned, by Prof. A. C. Scott, of the Scott Engineering Company, Dallas, Tex., while the engine was about its daily work in the operation of the power plant of the Hugo (Okla.) Ice & Light Company.

The engine had been in service something over six months when the test was made and there was no tuning up, or special preparation made therefor. The test extended over a period of three days and records were taken at all stages from no load to 10 per cent overload.

These records show a fuel consumption of 10.8 gal. of oil at $\frac{1}{4}$ load; 6.8 at $\frac{1}{2}$ load; easing down to 6.2 gal. at full load for 100 net brake hp-hours, or, 0.441 lb. of oil per net brake hp-hour, and a shade less at the 10 per cent overload.

The thermodynamic records taken, based on net useful output, show 17.4 per cent at $\frac{1}{4}$ load; 27.8 per cent at $\frac{1}{2}$ load; 29.5 per cent at $\frac{3}{4}$ load; 30.3 per cent at full load, and 30.2 per cent at 10 per cent overload.

There are no European records known to us which show better, and this speaks well for the American practice.

There have been installed so far over 60,000 hp Busch-Sulzer-Diesel oil engines in various lines of industry in twenty-five states and the Busch-Sulzer Bros.-Diesel Engine Company has now determined on building a large manufacturing plant at St. Louis, to add to the output of the American & British Manufacturing Company, at Providence, R. I., and the Power & Mining Machinery Company, at Cudahy, Wis., who have been building these prime movers for the Diesel Engine Company for some years.

This plant is now nearly completed, and will begin operations about June 1 next. It will, when finished and equipped, represent an outlay of over \$1,000,000, and will be one of the most up-to-date, and the largest plant in the United States devoted exclusively to the building of one type of engine.

Gould, Free and Ash is the name of a new firm of chemical engineers with offices in the Monadnock Building, San Francisco, Cal. Mr. Ralph A. Gould was formerly chief of the San Francisco Food and Drug Inspection Laboratory of the United States Bureau of Chemistry. Mr. Edward F. Free was formerly with the United States Bureau of Soils in Field Potash Investigations. Mr. Charles S. Ash was formerly chemist and assistant superintendent of the California Wine Association.

Evaporators for Export

One practice of the Swenson Evaporator Company, of Chicago, which deserves notice has to do with the shipment of goods to countries far distant from the place of manufacture. Two Swenson evaporators which were sent recently to South America on the order of Liebig's Extract of Meat Company, of London, England, were designed for the greatest possible simplicity in construction and operation, thus resulting in a minimum of attention and repairs.

At the same time, with each equipment were sent ten extra tubes, an extra vacuum gage, a full extra set of tube gaskets, extra peep-hole glasses, and additional special gaskets of all kinds. It is a practice of the Swenson Company to furnish these spare parts for foreign shipments because of the distance from the factory and the long time which would ordinarily be consumed in obtaining spares when for any reason they might be needed.

With the pumps were also sent a number of spares, for the same reason.

German Competition on the Smoke Problem

Since the results of the prize competition of Aug. 7, 1908, of the Department of Finance of Saxony as to the prevention of damage by smoke to agriculture and forestry has not been satisfactory, the department has decided to grant rewards for inventions which make it possible to render harmless to plants the gases coming off from furnaces and chemical works without in any way limiting the operation of the works.

Methods and apparatus which are only intended to produce a soot-free combustion will not be considered.

All applications will be investigated and an opinion given on them by the commission appointed by the Department of Finance for the investigation of the smoke evil.

Applications, which must be in German and which must contain any necessary drawings and analyses, should be addressed to the Königlich Sächsische Finanz-Ministerium, II. Abteilung, Dresden, Germany.

Rewards may also be granted for literary work intended to promote the solution of this problem.

The Smoke Abatement Problem

The Committee for the Investigation of Atmosphere Pollution, appointed at the International Smoke Abatement Conference and Exhibition held in London last March, has held three meetings in London and has just published what may be regarded as an "Interim Report."

This report states that after careful consideration of all the various methods that have been suggested or tried for measurement of the impurities of the atmosphere, that employed for the *Lancet* investigation of the soot and dust fall of London in 1911, has been selected as the simplest, and the one most likely to yield satisfactory results, under the conditions which will govern the observations that are to be made. The method is based upon the use of an apparatus resembling an enlarged rain-gauge, with a catchment area of 4 sq. ft. This gauge receives all the dust and soot that falls by its own weight, or is carried down by the rainfall during the period of its exposure, and on examination of the water which collects in the bottle attached to the apparatus, the amount of total suspended matter, tarry oils, soot, etc., can be determined.¹ A circular letter has been sent out by the committee to all the more important city and local authorities in the United Kingdom asking for their co-operation in the application of this method of observation in districts over which they have administrative powers.

This circular has met with a most gratifying response. The authorities of a large number of important cities have already signified their intention of commencing observations on the lines suggested by the committee, and many other authorities are only waiting for further details, before promising their

¹We intend to describe the apparatus more in detail in a future issue.

support to the movement, and also co-operation in the work.

Birmingham, Bradford, Leicester and Newcastle are the most important of the cities that have definitely promised their support; but there is no doubt that Glasgow, Liverpool, Manchester and London will join in these observations.

The new movement that has been initiated by the committee for studying and recording the character of the soot fall in various industrial centers of the United Kingdom, is therefore meeting with considerable support, and there is little doubt that the observations and records will prove of considerable value to all interested in the progress of smoke abatement.

Dr. W. N. Shaw, F. R. S., of the Meteorological office, is chairman of the committee; and its secretary is Dr. J. S. Owens, 47 Victoria Street, S. W., from whom any further particulars regarding the work of the committee can be obtained.

Annealing Furnace and Electric Steel Furnace

The Midvale Steel Company of Philadelphia, Pa., has ordered a battery of six large Stobie annealing furnaces for the heat treatment of tool steel bars. The installation will be the largest in the world for this class of work, having a total capacity of 7500 tons of steel bars per year.

It is about six years since Mr. Victor Stobie, of Sheffield, erected in that town the first of the then, newly invented furnace for annealing tool steel bars, which had been designed by him. Since that date, in addition to the many furnaces working in Sheffield, a considerable number of furnaces has been erected in steelworks in all parts of Germany and Sweden, including the biggest Continental steel concerns such as Krupp, of Essen, Baidonhutte, of Kattowitz, Lindenburg, of Remscheid, Bismarckhütte, of Schwientochlowitz, Oberschlesische Eisen, A. G., of Gleiwitz, Hofors, A. B., of Sweden, etc.

At the plant of the Midvale company the furnaces are producer-gas fired, the gas being manufactured in plant attached to the main structure. Such gas costs about 1.5 cents per 1000 cubic feet and offers the advantage of being under as good control as a gas kitchen range. The furnaces are built underground, and can be regulated in fifty to one hundred sections according to the length of each furnace.

A few notes should be added on some recent work by Mr. Victor Stobie on electric steel. As has already been noticed in this journal, a big all-electric steel works is being erected on Tyneside by Mr. Stobie which will be all British from foundation to roof. The electric furnace has been designed by Mr. Stobie to "embrace all the features which are looked upon as essential by the expert Sheffield steel maker." No detail of construction are yet available. But it is stated that a 5-ton Stobie electric steel furnace is shortly to be erected in a German steel works.

Pulverizing Coal

Elsewhere in this issue will be found a very interesting article by Mr. H. G. Barnhurst, of the Fuller Engineering Company, of Allentown, Pa., on the proper methods of using powdered coal as fuel.

This subject is attracting very considerable attention at present as a result of the rise of the price of crude oil, and in this connection the matter of the cost of pulverizing coal becomes important. Any figures from practice on the cost of pulverizing coal should, therefore be welcome.

We are obliged to the Bradley Pulverizer Company of Boston, Mass., for the following figures obtained with Griffin mills in cement plants.

The 30-in. Griffin mill has been used for the past 24 years as a coal pulverizer. The "Giant Mill" has been on the market but three years, but in the short period has demonstrated that it is a very economical mill. It is really an enlarged 30-in. mill designed with the view of giving a larger output and has many improvements which past experience has advised. The Giant mill is now used in many important cement plants for grinding cement rock, slag, cement clinker, and coal.

At the plant of the Penn Allen Cement Company, Penn Al-

len, Nazareth, Pa., where 30-inch Griffin mills are used, the horsepower consumed is from 18 to 20 hp, the fineness 95 per cent through 100-mesh screen, the output approximately 1½ tons per hour, the cost of up-keep about ¼ cent per ton.

At the plant of the Cape Girardeau Portland Cement Company, Cape Girardeau, Mo., where 30-in. Griffin mills are used, the horsepower consumed is 25 to 30 hp, the fineness 93.2 per cent through 100-mesh, the output 2.67 tons per hour.

At the plant of the Iola Portland Cement Company, Iola, Kan., where 30-in. Griffin mills are used, the horsepower consumed is 25 hp, the fineness 95 per cent through 100-mesh, the output better than 1½ tons per hour.

At the plant of the Knickerbocker Portland Cement Company, Hudson, N. Y., where Giant Griffin mills are used, the horsepower consumed is from 40 to 50, the fineness 94 per cent through 100-mesh, the output over 3 tons per hour, the up-keep "practically nothing."

One of the largest users of Giant Griffin mills for pulverizing coal states that they are procuring an output of from 3 to 5 tons per hour to a fineness of from 90 to 95 per cent through a 100-mesh screen depending on dryness and texture of coal, since, of course, the output of any mill is regulated by dryness and character of material.

Calendars, Diaries, Directories

Calendar.—We have received an attractive calendar from the Lead Lined Iron Pipe Company, which shows several pictures of their lead-lined iron pipe and lead-lined iron valves. This calendar also gives some interesting information about a few of the many installations of their pipe and valves. It will be mailed to interested parties.

American Cement Directory.—We have received from the Bradley Pulverizer Company, Boston, Mass., their very useful American Cement Directory for 1913, compiled by the Technical Press of Boston, Mass. Besides illustrated notes on the Griffin mills, made by the Bradley Pulverizer Company, it contains an alphabetical list of Portland cement plants in operation in this country with the names of officers.

The Badger Chemical Diary is a new annual published by the E. B. Badger & Sons Company, of Boston, Mass., which should prove exceedingly welcome to chemical engineers. Besides illustrated notes on the various chemical apparatus made by this company (evaporation, vacuum pans, stills, dryers, autoclaves and digestors, lead-and-silver-lined apparatus, etc.), it contains useful engineering data on specific heats, expansion coefficient of liquids, properties of various chemicals, strength of materials, properties of saturated steam, heating data on various fuels, conversion tables, etc. It also contains a set of maps and a diary. The intention is to enlarge the engineering data in future issues. But as it is, this first edition marks an excellent beginning.

Personal

Mr. M. W. Atwater, of Butte, Mont., has recently resigned his position as general manager for the Butte & Superior Copper Company, to accept the management of the Davis-Daly Copper Company. He succeeds Mr. William B. Fisher, who has resigned.

Mr. James L. Bruce, general manager for the Continental Zinc Company, Joplin, Mo., is assisting Mr. J. R. Finlay in the examination of the St. Joseph and Doe Run lead mines in southeastern Missouri.

Mr. C. F. Buck has been appointed chief engineer and superintendent of construction for the Dominion Nickel Copper Company, and will have charge of the design and construction of a new smelter at Sudbury, Ont. Mr. Buck built the Hayden smelter of the American Smelting & Refining Company, and rebuilt the Tacoma plant of the same company.

The Colorado Chapter of the American Mining Congress, at its annual meeting, elected the following officers and three

tors for 1913: Governor, S. D. Nicholson, Leadville; first lieutenant governor, J. M. McClave, Denver; second lieutenant governor, A. L. Burris, Cripple Creek; third lieutenant governor, Bulkeley Wells, Telluride. Executive Committee: V. C. Alderson, Golden; R. L. Martin, Central City; Thomas Tonge, Denver; secretary and treasurer, E. L. Wolcott, 725 Majestic Building, Denver. Directors: D. W. Brunton, Denver; E. W. Bosco, Creede; E. A. Collum, Denver; R. D. George, State Geologist, Boulder; A. W. Harrison, Silverton; R. M. Henderson, Breckenridge; Irving Howbert, Colorado Springs; W. E. Renshaw, Idaho Springs; John T. Roberts, Jr., Ouray; G. S. Wood, Cripple Creek.

Mr. Karl Eilers is making a tour of inspection of the smelters of the American Smelting & Refining Company, and expects to return to New York about the last of March.

Mr. Robert M. Keeney has been appointed electro-metallurgist of the Bureau of Mines, and will be stationed at Pittsburgh. He will be engaged for the present on experimental work in the treatment of non-ferrous ores in the electric furnace.

Mr. Frederick Laist has been appointed general superintendent of the Anaconda smelter of the Anaconda Copper Mining Company, succeeding Mr. William Wraith.

Mr. Richard K. Meade has opened an office and laboratory at 202 North Calvert Street, Baltimore, Md. Special attention will be given to lime and cement.

Mr. Uley Wedge recently made a trip to the cities on the the Pacific coast.

Mr. William Wraith, who has been general superintendent of the Washoe plant of the Anaconda Copper Mining Company for many years, has been made general manager of the International Smelting & Refining Company, and will reside in Salt Lake City. He assumed his position on the first of this year.

Digest of Electrochemical U. S. Patents

Prior to 1903.

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

ORE TREATMENT (Continued).

669,752, March 12, 1901, Paul W. Knauf, of Philadelphia, Pa., assignor to The Electrical Lead Reduction Company, of same place.

Relates to apparatus for electrical reduction of lead sulphide, etc., and consists of a series of preferably cone-shaped pans of antimonial lead, superimposed, so that a gas-tight and insulated joint is made between the several pans. Within each pan is a removable insulating lining, covering the sides, and restricting electrolytic action to the bottom of the pan. The pans are supplied with a suitable quantity of lead sulphide and 10 per cent sulphuric acid, the top pan connected to the positive pole, and the bottom to the negative pole. When a series of such pans are thus connected, the bottom of an upper pan constitutes the anode, and the lead sulphide the cathode; hydrogen liberated by electrolysis reduces the lead sulphide to metallic lead, and forms hydrogen-sulphide which passes out through a vent to a stack.

669,926, March 12, 1901, Carl Hoepfner, of Frankfort-on-the-Main, Germany.

Relates to a method of depositing zinc from a solution in a three-compartment cell. The cell consists of a plurality of U-shaped sections, separated by diaphragms, all bolted together. Every anode and cathode compartment is connected in series by passages, so that the anode electrolyte circulates through anode compartments, and the cathode electrolyte through cathode compartments. The intermediate compartments are also connected by passages, either in series or in parallel. The level of the solutions is so regulated that the catholyte is at

a higher level than that of the intermediate cell and still higher than that of the anolyte. There is therefore a constant diffusion of solution from the cathode compartment toward the anode compartment, which prevents contamination of the catholyte by the anolyte. The anode is a metal soluble in the anolyte, and electronegative to zinc, as lead or copper. On dissolving, it forms nitrates, acetates, etc., according to the electrolyte used, and after circulating through the several compartments, is precipitated in a suitable vessel outside of the cell, by a zinc salt as zinc sulphate, zinc carbonate, etc. The solution freed of lead, etc., is now used as the catholyte. The intermediate compartment is supplied with a solution preferably identical with the catholyte, and contains a separator which is electrically connected to the cathode through a resistance. As anodes, impure lead or copper ingots may be used, and the metal subsequently precipitated is highly pure and may be suitably reduced or otherwise treated. Any lead or copper that diffuses into the intermediate compartment will be precipitated by electrolysis; or the intermediate electrolyte and catholyte may be further purified by zinc dust. All of the electrodes are constantly vibrated to assist stirring and depolarization.

677,089, June 25, 1901, John C. Kessler, of Milwaukee, Wis., assignor of one-half to Christian Wahl, of same place.

Relates to the extraction of native copper from precious metal tailings by a leaching solution containing a cupric ammonium compound, such as cupric oxide, cupric sulphate, etc., dissolved in ammonia. The tailings or pulverized ore is placed in a leaching tank and covered with the cupric ammonium solution; this is then covered with about 4 in. of water which prevents loss of ammonia by evaporation. After 24 or 48 hours, the lower ammonia solution is run off, and the ore covered with water to wash it. The cupric ammonium solution dissolves copper forming cuprous-ammonium compounds, as follows:

This solution thus obtained is electrolyzed, precipitating half of the copper, the remainder being oxidized to the cupric state and reused.

678,526, July 16, 1901, Charles P. Stewart, of Oakland, Cal.

Relates to an apparatus in which gold, etc., is electrolytically deposited from a flowing cyanid solution upon a quiescent body of mercury. The apparatus consists of a long shallow trough or tank through which a cyanid solution flows. The bottom of the trough is covered with a layer of mercury electrically connected as a cathode; a number of separate anodes are adjustably suspended in the solution, the adjustment providing for any irregularities in wear. When the mercury is saturated it is removed and the precious metals separated in any suitable manner.

682,155, Sept. 3, 1901, Charles P. Tattno and George Delms, of Seattle, Wash.

Relates to an apparatus for extracting precious metals, and refers to their prior patents 640,718 and 653,325. This apparatus consists of a suitable acid-proof tank having a copper pan covering the bottom, and a mercury cathode in the copper pan. Above the mercury are rotating paddles which keep the pulp and solution well stirred. Above the paddles are a number of depending carbon anodes, supported by a lid. The lid, anodes and paddles are capable of being raised vertically from the tank to facilitate charging, etc. A supplementary anode projects through the side of the tank and serves to keep current continuously electrolytically protecting the mercury and copper from corrosion when the main current is cut off. When the operation is completed, the tank is emptied through a spout in the bottom.

682,018, Dec. 17, 1901, William Orr, of Salt Lake City, Utah, assignor to The Gold and Silver Extraction Company, of America, Ltd., of Denver, Col., a joint stock company in Great Britain.

Relates to a method of regenerating cyanid solutions, particularly those containing copper and zinc cyanids, and an apparatus to electrolytically precipitate the copper. The apparatus consists of a tank having a plurality of pairs of electrodes, alternate ores of zinc connected as anodes, and the intermediate

ones of copper, connected as cathodes. The solution flows between the electrodes, the copper being deposited and an equivalent of zinc going into solution. To the solution now containing zinc cyanid is added an alkaline or alkaline earth hydroxid, forming, for example, sodium zincate. To this solution is added just enough sodium sulphide to form zinc sulphide which separates, and may, if desired, be filtered off and recovered. The solution now consists of the original cyanid plus some alkaline or alkaline earth hydroxid, and is used in the usual manner for treating ores.

689,070, Dec. 17, 1901, Alexander Stanley Elmore, of London, England.

Relates to the separation of mineral substances by the selective action of oil, and states that in the presence of an acid the separation is more effective. The apparatus used consists of a mixer, a settling tank, and a centrifugal separator. The ore is suitably powdered and is supplied to the mixer with five to ten times its weight of water, forming a thin freely flowing pulp. To the mixer is also added a thin stream of oil, and an acid soluble in oil but insoluble in water, such as oleic acid which together with the oil coats the metallic particles, such as metal dust, tellurids, sulphides, graphite and elemental sulphur, with a film of oil, thereby causing them to float. Instead of oleic acid, or a similar acid, an acid soluble in water but insoluble in oil, such as sulphuric acid, may be used. The quantity of acid added, in either case, will vary with the materials being separated; in some cases it may be as little as 1/500 part of the oil or water used.

689,674, Dec. 24, 1901, Albert Isaiah Irwin, of Cripple Creek, Col., assignor of one-third to Caleb F. Bryant, of Cripple Creek Mining District, Teller County, Col.

Relates to apparatus for electrolytically dissolving and precipitating the metallic content of an ore. The electrolytic apparatus consists of a traveling endless belt, of metal, on which are cross-pieces of insulating material. The movement of the belt conveys the ore through a suitable solution, and discharges it from the machine. The belt is connected as an anode, and adjacent thereto are cathodes. With gold ores, a cyanid solution may be used as electrolyte, the dissolved gold and silver being electrolytically deposited. If the ore gives an acid reaction to water, sufficient alkali is added to maintain the alkalinity of the electrolyte.

689,959, Dec. 31, 1901, Edward Leslie Graham, of Upper Warrlingham, England.

Relates to the disintegration and comminution of ores, etc., by the action of gases generated by passing an electric current through a suitable acid solution, such as sulphuric, hydrofluoric, or mixed sulphuric and hydrofluoric. Other acids and salts may also be added, such as ammonium chlorid or carbonate, barium chlorid, fluorspar, etc. With free-milling gold ores, 2% per cent of sulphuric acid and 1 per cent of hydrofluoric acid are said to give good results; other ores, such as those of copper, silver, and antimony, require different percentages. The current strength will vary with the ore and size of the vat, and should have a voltage of about fifty volts per vat.

Book Reviews

Die Spezialstähle. Ihre Geschichte, Eigenschaften, Behandlung und Herstellung. By G. Mars, Dipl.-Ing. Octavo (15½ x 24 cm.), 517 pages, 143 illustrations; price 17 marks, bound 18.40 marks. Stuttgart: Ferdinand Enke.

A monumental treatise by the director of the research department of the Rhenish Metalware & Machinery Works, in Düsseldorf. It is far more than a mere compilation, for the author discusses in a very instructive manner the relations of the steels to each other, the bearing of the periodic system of the elements on the effects produced by different metals, and even reflects upon the somewhat neglected question of the improvement of these steels by proper treatment of the fluid metal.

After chapters on history, metallography, the iron-carbon diagram, heat treatment, forging and cold-working of steels, the author takes up in distinct chapters the carbon, Si, Mn, Cr, Mo, W, V, Ti, Al, and Ni steels, and more briefly, in two chapters, the V, Ta, B, Sn, Co and Cu steels. There are also separate chapters on construction steel, high-speed tool steel, and (76 pages) on the manufacture of the special steels.

The whole is worked over with great accuracy and completeness. Friends of the electric furnace steel will read with satisfaction the verdict of this expert upon the rôle of the electric furnace in the manufacture of these special steels: "The electric steel smelting process appears to be undoubtedly the highest stage in the development of steel manufacturing processes."

* * *

Metallurgische und technologische Studien über das Ausglühen von Metallen und Legierungen. Von Dr. Ing. Max Weidig. Large quarto (22½ x 30 cm.), 121 pages, 48 illustrations; price 6 marks. Berlin: Leonhard Simion Nf.

The author is privat-docent at the Bergakademie, Freiberg. In one-half of the book he reviews the results of others on the influence of annealing upon the structure and mechanical properties of metals and alloys; in the second half he relates his own experiments upon nine materials: copper, nickel, copper-nickel, brass, aluminium bronze, tin bronze, tin-zinc bronze, german silver, and aluminium. Each of these materials were tested hard and annealed, and the effects on color, luster, structure, hardness, tensile strength, ductility, and electrical conductivity carefully determined.

An interesting observation is the relative quantities of heat energy absorbed in annealing slowly at a low temperature, and quickly at a higher temperature. Using an electric furnace for heating, it is usually more economical of power to anneal quickly at the higher temperature. This is only one of many useful items of information in this monograph.

* * *

Transactions of the American Foundrymen's Association: Vol. xx. Edited by Richard Moldenke, Secretary. Octavo (15 x 23 cm.), 684 pages, numerous illustrations. Watchung, N. J.: The Association.

A fine collection of mostly short papers, dealing with details of foundry practise up to the theory of alloys. An 18-page paper, finely illustrated, on the use of the induction furnace for making steel castings, by Mr. C. H. Vom Baur, is a notable contribution to that subject; a paper on pyrometry, by Mr. S. H. Stupakoff, also deserves mention. Many of the others are well worth reading, although the English and the manner of presentation are frequently faulty. The printing and binding are excellent.

* * *

Die Praxis des Eisenhüttenchemikers. By Dr. Carl Krug. 15 x 23½ cm., 226 pages, 31 illustrations; price 6 marks. Retail price New York, \$2.00. Berlin: Julius Springer.

Chemische Untersuchungsmethoden für Eisenhütten und deren Nebenbetriebe. By Ing. Albert Vita and Dr. Carl Massenez. 13 x 21 cm., 175 pages. Price 4 marks. Retail price New York, \$1.35. Berlin: Julius Springer.

Dr. Krug is "Dozent" in the "Bergakademie" in Berlin. His book is the product of 15 years' teaching experience, and is very carefully and painstakingly written. Engineer Vita is chief chemist for the Friedenshütte in upper Silesia, and Dr. Massenez teaches analysis in the Technical High School of Breslau. Their book is the product of practical experience, omitting all methods which have been superseded in recent years.

Both works are commended to the iron and steel works' chemist. Science is the most truly international factor in modern life, and the scientific man has the widest opportunity to become cosmopolitan in his profession if he will only avail himself of such assistance and information as are at his disposal. Thus, a mere bagatelle of ten marks will put him abreast of the best European practice in iron and steel works' laboratories.

The Haber Synthetic Ammonia Process

At last year's International Congress of Applied Chemistry Dr. Bernthsen made the important announcement that the problems involved in the Haber synthetic ammonia process have been "solved fully on a manufacturing scale and that the walls of the first factory for synthetic ammonia are already rising above the ground at Oppau, near Ludwigshafen on the Rhine." The report which Professor Haber made to the Badische Company three years ago and which led to the development of the process by this company on a large scale, has now been published and a rather full account of it is given elsewhere in this issue. It is a historic document and calls for comment on the commercial, technical, and scientific aspects of the process.

From a commercial standpoint the process has various very attractive features. As mentioned in the beginning of Prof. Haber's report, there is a large margin between the value of the ammonia and the value of the raw materials, hydrogen and nitrogen. In the form of 25 per cent ammonium sulphate the ammonia is estimated to be worth 22.25 cents per kilogram, while the cost of the nitrogen and hydrogen in it is estimated at $1.125 + 4.375 = 5.5$ cents. In view of the comparative simplicity of the process and the low power requirements it is hardly risky to say off-hand that this margin is large enough to pay manufacturing cost and a good profit.

A second attractive commercial feature is the fact that with the rapid increase in the consumption of fertilizers in recent years over-production and a drop of prices due to over-production seems a practical impossibility for years to come. Taking nitrogen fertilizers alone and taking nitrate and ammonia together, Bernthsen finds that there has been an annual increase in consumption of 38,000 tons of nitrogen, corresponding to nearly 185,000 tons of ammonium sulphate. Clearly enormous quantities of synthetic ammonia must be produced to affect the nitrogen fertilizer market. This explains why Dr. Bernthsen was emphasizing that the development of the new industry would not take place at the cost of other branches of industry and commerce. It may also explain why the Badische Company has withdrawn from the Norwegian electric-furnace nitrate field. Synthetic ammonia is a big enough proposition even for a very big company.

From a technical viewpoint it is interesting to compare the synthetic ammonia process with the electric-furnace processes of making nitrate and of making calcium cyanamide. The latter two employ a very high temperature and their power requirements are high. The ammonia process employs a comparatively moderate temperature—between 500 and 700 deg. C.—and its power requirements are low. From a technical viewpoint the most interesting and novel features are the use of a high atmospheric pressure and the circulation of the high-pressure nitrogen—

hydrogen gas mixture between a furnace (where the ammonia is formed) and a refrigerator (where the ammonia is liquefied and withdrawn).

Even more interesting, perhaps, is the process from a scientific viewpoint. The process will go into history as one of the biggest achievements of modern physical chemistry. Without modern physical chemistry, based on thermodynamics, the process could never have been developed. The one fundamental problem was, indeed, of a thermodynamical nature; it was to find the best temperature and the best pressure for the reaction. How keenly Professor Haber attacked the thermodynamic equilibrium problem and how systematically he solved it, is appreciated by all who know his classical *Vorlesungen über technische Gasreaktionen*. But there was another fundamental problem to be solved which is intimately connected with the first problem. This was to find the best catalyst to get a sufficiently high reaction velocity. How the thermodynamic equilibrium and the reaction velocity influence the choice of temperature and pressure is admirably brought out in the report.

Admirable, too, is the systematic perseverant research of Professor Haber and his co-workers on the effectiveness of various catalytic agents. But the successful and clever way in which the periodic system of the elements is made use of in this research, makes the mystery of the nature of catalytic action only more mysterious and more interesting. Why should certain elements accelerate the reaction? Why should other materials (Bernthsen's "poisons") retard it? Why should the effective catalytic agents be found in certain groups of the periodic system of elements? Why should, in these groups, the elements with highest atomic weights be the best catalytic agents? There is no end of why's and apparently there is no answer. Thus, while the process emphasizes the importance of the advances made in physical chemistry in recent years, it also emphasizes the limitations of our theoretical knowledge.

Professor Haber is no stranger to American chemists. Especially among American electrochemists he has many friends and admirers. Ten years ago he attended the first Niagara Falls meeting of the American Electrochemical Society, and his able report to the Bunsen Society on the American electrochemical industries is unforgotten. In his hour of triumph his American friends sympathize with him and extend to him their hearty, sincere congratulations.

Engineers, Practical Men, and Theories

In his presidential address before the Colorado Scientific Society, Mr. George E. Collins recently made some pertinent remarks about the practical application of hypotheses and theories. Although Mr. Collins was speaking particularly of mining and not of metallurgy, it would require only a simple substitution of terms to make his comments equally pertinent to ore treatment. Comparing the so-called "practical man" with the professional engineer, Mr. Collins showed that while the former often scoffs at the ideas of the latter, regarding him as a theorist, nevertheless the practical man "also plans his work along the lines suggested by some hypothesis. The trouble is, as has been pointed out by others, there is no theorist so wild or so inveterate as your practical man; none that rides his hobby so hard or so far." This must call to the memory of every

engineer some experience with a "practical theorist"; as, for example, the man who knows that the fire assay for gold is unreliable for *his* ore; or the one who confided to us that the presence of "telluride of quick" in his ore was the principal metallurgical obstacle to its successful treatment. More serious in their consequences are the theories of subordinates in metallurgical works, who frustrate the plans and tests of their superiors because of an abiding faith in their own ideas.

Following Mr. Collins by analogy: What is needed for progress in ore treatment is the trained mind, acquainted with the literature of the subject, able to observe and to correlate and interpret results, and familiar with all the ideas of others which might have a bearing on his problem. Thus equipped, the individual will be able to form rational hypotheses on which to base experimentation. He will know when to pursue and when to abandon a line of investigation, and will be able to balance the probability of failure with the possibility of success. With all justice and consideration for the practical man, the need of the day is the trained mind.

Grinding Machines

The respective merits of the four principal types of grinding machines, rolls, and Huntington, Chilean and tube mills, have been the subject of many general discussions and some comparative tests. But despite the work that has been done in this line, the fact remains that no adequate comparative test of all the machines has ever been made, whereby the various factors of efficiency, such as power consumption, cost of operation and suitability of product, could be compared. Competitive tests in individual instances have determined the choice of machines for those particular cases, which is perhaps the best way of eliminating the less desirable machines and determining which is fittest to survive. In this way we have secured some good data, and have arrived at certain practical conclusions.

The increasing popularity of the tube mill as a secondary grinding machine, directs attention toward the deficiencies of the other types mentioned. Generally speaking, the objection to rolls is their failure to deliver a finished product in one operation, with the result that oversize in considerable quantity must be returned to the same machine. This, in turn, entails poor sizing in the trommels, and builds up feed at this point in the mill system to a tonnage which usually is considerably greater than the original feed to the mill. This condition could be avoided by a screen-faced machine with fixed maximum size of discharge, such as a Chilean mill; but a new factor would be introduced in the form of excessive slime production, which might be decidedly detrimental to the subsequent treatment of the ore. Rolls give a more granular product for concentration, the middling from which can be further ground to liberate the mineral; and for this reason rolls have been widely adopted in concentrating mills. On the other hand, the Chilean mill has been successfully used in copper concentration, for grinding an ore which must be finely divided in order to free the disseminated mineral from the gangue. But in these cases, excessive sliming has been avoided by grinding in stages, using coarse screens on the mills, and regrinding the coarser sizes of sand.

The Huntington mill works well on soft ore, but is not properly constructed to be of much effect on hard ore. It lacks the positive action of the Chilean mill or rigid rolls, and hence has little effect on an ore which is hard enough to resist crushing by the centrifugal force of the rollers against the die. On the whole, it is a rather complicated machine, which requires careful attention and the exercise of good judgment in its operation. One operator at Park City, Utah, has secured better results from this mill by connecting the upper ends of supports of opposite rollers by means of rods and a turnbuckle, thereby holding the rollers positively in position against the die.

The tube mill, and its close relative, the ball mill, are likely to displace the Huntington mill altogether, as well as make inroads on the former domain of the Chilean mill and rolls. These two machines, especially the Hardinge type, have been widely adopted as secondary grinders in concentration. They are attractive on account of their simplicity, absence of the wearing parts so common to other grinders, and the ease of replacing the grinding medium. Even for small mills the combination of a coarse crusher, ball mill and tube mill, each adjusted to produce a definite crushing effect, and thereby eliminating troublesome screens, offers such a simple and efficient means of preparing ore for different forms of treatment that it should receive attention.

The Steel Corporation's Report

The United States Steel Corporation's report for the year 1912 shows very substantial progress toward the full realization upon the improvements and extensions it has been making. The output in steel products, weighed in the form in which sold to the public, was 12,506,619 tons, an increase of no less than 1,772,624 tons over the best previous year, which was 1910. While the corporation's capacity was not fully engaged in 1912, the output was approximately only about a million tons less than capacity.

The corporation is able to meet its interest and dividend charges with very much smaller profits per ton than when it was formed, for its capacity when formed April 1, 1901, was only 8,000,000 tons, over which its actual output in 1912 was a gain of 56 per cent., while its present capacity represents a gain of between 70 and 75 per cent. Concurrent with this increase in capacity and in actual output there has been a relatively small increase in capital obligations. At the start the bonds, both of subsidiary companies and of the steel corporation itself, together with the common and preferred shares outstanding, made a total face value of \$1,400,000,000. To-day the securities outstanding amount to \$1,513,000,000. The sinking fund, interest and dividend charges have increased in hardly as great ratio. At the outset the corporation paid 4 per cent. dividends on its common stock, but assuming 5 per cent., to make a comparison with the present dividend at that rate, the sinking fund, interest and dividend charges were approximately \$85,000,000 a year; to-day they are \$91,500,000. This latter sum includes the interest paid on bonds which are carried in sinking funds, but the face value of such bonds is not included in the \$1,513,000,000 of outstanding securities already mentioned. The charges of 1901 represented \$10.60 per ton of output at capacity, while

the charges to-day represent \$6.65 per ton of output at capacity. The total earnings in 1912 represented \$9.45 per ton of actual output. The earnings covered all charges and left a slight balance for surplus, \$3,605,247.

Wall Street studies the annual reports of the Steel Corporation with much interest and pays attention to summaries of the amounts which the corporation has invested in plant betterments and extensions, for the purpose of illustrating the extent to which the corporation has "squeezed the water" out of its capitalization. The practical steel manufacturer realizes such summaries are inconclusive without adequate study also with respect to the depreciation charges which have been allowed, and on account of the vicissitudes in the steel industry it is impossible to be certain at any time how much depreciation should be allowed. While the view is apparently very superficial, it is probably much more accurate, if not so precise, to summarize the Corporation's position in this way, that it undoubtedly requires a larger capital investment to manufacture a ton of finished steel economically to-day than it did 12 years ago, when the Corporation began business, yet we find the actual showing is that in this period the Corporation has increased its capital obligations and its annual charges only 8 per cent., while it has increased its productive capacity between 70 and 75 per cent.

Since its early days the Steel Corporation has made an annual offering of its shares to employees, naming a price somewhat under the current market figure, to be paid upon the installment plan, but to bear dividends from the date of subscription. The offering of January, 1913, resulted in subscriptions by 36,119 employees, for 34,551 shares of preferred and 25,793 shares of common stock, representing respectively 0.96 and 0.49 per cent. of the total shares outstanding. Under the latest subscription, subscribing employees receive a bonus of \$5 a year on preferred shares and \$3.50 a year on common shares, as long as they retain the stock and remain in the employ of the corporation, up to a period of five years, at the end of which time the bonus which would have inured to those who dropped out is divided among the survivors. It would be interesting to know the situation at present as to participants in previous distributions, how much stock is retained by the original subscribers, the classes respectively whose bonuses have expired and whose bonuses continue. An accurate statement as to the former would, of course, be impossible, as shares sold are not always transferred on the books.

The Corporation's years of largest output were 1910, with 10,733,995 tons, and 1912, with 12,506,619 tons, showing a gain for 1912 of 16.5 per cent. over the record. There were great changes in the distribution of output, for some products actually lost in tonnage, while others made great gains. Rails lost more than 12 per cent. In minor railroad products there was a large increase in axles, but almost as large a loss in steel car wheels. The most important gain was in sheets and tin plates, 39 per cent., while tubular goods showed an increase of 28 per cent. On the whole it is readily observed that the Corporation carried its tonnage to a higher degree of finish, on the average, in 1912 than in 1910, so that the physical value of its output increased more than the 10.5 per cent. which the tonnage increase represented.

Readers' Views and Comments

Simple Approximate Rules for Temperature Conversions

To the Editor of *Metallurgical & Chemical Engineering*:

Sir.—The following simple, easily remembered, approximate rules for mentally converting high temperatures in Fahrenheit degrees into one in Centigrade degrees and the reverse, may be of interest to those dealing with furnaces; the troublesome factor 5/9 is thereby evaded. Whether they are already generally known or not in this form, the writer does not know.

Double the Centigrade temperature and deduct one-tenth of that figure, (or deduct to per cent, then double it). Thus 1000 deg. C. doubled is 2000, less a tenth (200) leaves 1800 deg. Fahr. For all ranges the error is that this value is always 32 deg. too small; hence it may be made accurate by adding 32.

Halve the Fahrenheit temperature and add one-tenth of that figure (or add 10 per cent, then halve it). Thus, 2000 deg. Fahr. halved is 1000, plus a tenth (100) gives 1100 deg. C. Accurately it is 1093.3+; hence the approximate value is only about 1/2 of 1 per cent too high. Again 3000 deg. Fahr. halved is 1500, plus a tenth (150) gives 1650 deg. C. Accurately it is 1648.9—; hence the approximate value is less than a tenth of 1 per cent too high. For the lower temperatures the errors become greater.

If 32 is first deducted from the Fahrenheit values, then the values given by the latter rule are always almost exactly 1 per cent too low for all ranges, hence could be made nearly absolutely correct if desired by adding 1 per cent.

These rules are easily remembered as it is well known that the Fahrenheit values are *not quite* double the Centigrade ones, hence something must be *deducted* after doubling the Centigrade values, or must be *added* after halving the Fahrenheit values; and that this correction factor is 10 per cent is easily remembered as this is the simplest possible of all factors, being merely a shift of the decimal point.

The mathematical proofs of these rules are very simple, as the correct factors are 5/9 and its reciprocal, beside the 32

Philadelphia, Pa.

CARL HERING.

Determination of Oxygen in Iron and Steel.

To the Editor of *Metallurgical and Chemical Engineering*:

Sir.—In the February number of *METALLURGICAL AND CHEMICAL ENGINEERING* appears an article by Mr. R. H. McMillen, on the application of the electric resistance furnace to the determination of oxygen in iron and steel.

The writer's¹ modification of the Ledebur method (*Jour. Ind. & Eng. Chem.*, vol. 3, p. 372), is referred to, and the double electric furnace as well as certain other modifications are proposed as improvements.

The laboratories under the writer's supervision have had probably a larger and wider experience with the determination of oxygen in iron and steel than any other in this country. In our opinion the modifications proposed by McMillen present no improvements over the process used by us, and are open to criticism in respect to several important points. In a routine laboratory where a large number of oxygen determinations have to be made, the time element is of great importance. With the gas blast furnace using a silica tube it is possible to cool down immediately by turning on the cold air blast, so that accurate results can be obtained in one-half hour. The double electric furnace modification runs the test for a full hour, and if the analysis is started with a cold furnace, it will require an hour to reach the specified temperature of 950 deg. C., whereas the gas blast furnace can be brought to temperature in a few minutes. In our practice we often exceed this temperature and have never found that we obtain higher results with the higher temperature.

McMillen proposes the use of a porcelain boat instead of the nickel boat used by us. We especially avoided the use of porcelain, owing to the tendency of that material to adsorb moisture from the air.

The most important criticism of McMillen's modification that we have to offer is with respect to weighing the phosphoric acid absorption tube filled with hydrogen. We believe this to be bad practice, and numerous tests made in this manner have shown discordant results owing to the tendency of hydrogen to diffuse through "air-tight" stoppers.

The McMillen method is almost identical with the one published by the writer, with the exception of the points discussed above, and for the reasons stated it does not appear that any contribution has been made to the older method. McMillen again points out the well-known fact that the Ledebur method will not determine total oxygen, owing to the fact that certain oxides and silicates are not reducible by hydrogen. Walker and Patrick have proposed a method for determination of total oxygen, by making use of a vacuum electric furnace of the Arsem type. (Paper before Eighth Intern. Congr. of Appl. Chem., *Met. & Chem. Eng'g.*, vol. X, p. 629.) The installation for this method is very expensive and at best it could hardly become a routine determination in any chemical laboratory. On the other hand, it should not be forgotten that in most cases it is only the determination of oxygen combined with iron that yields the data desired, and it is this information which can be readily obtained by the Ledebur method. The amount of oxygen combined with silica and other oxides unreducible by hydrogen has no bearing on the question as to whether iron or steel is properly deoxidized in the process of manufacture.

ALLERTON S. CUSHMAN

Institute of Industrial Research,
Washington, D. C.

* * *

To the Editor of *Metallurgical & Chemical Engineering*

Sir:—In the criticism of Dr. Allerton S. Cushman upon my article, "An Application of the Electric Resistance Furnace to the Determination of Oxygen in Iron and Steel," published in your February issue, he objects to the use of the electric resistance furnaces in my modification on account of the time required to bring the furnaces to a full heat and to cool them after the combustion is completed, thereby curtailing the number of daily determinations.

I consider that the advantages offered by this method more than compensate for the time lost, when the convenience of this means of heating is taken into account, and also the little attention the furnaces require. After the operation is started and until the combustion is completed, the operator is practically free to attend to other duties, so that very little of his time is counted against the oxygen determination. When the number of daily determinations to be made requires it, more furnaces can readily be added, using the one preheating furnace for all.

Dr. Cushman next objects to the use of the porcelain boat on account of the moisture absorbing tendency of this material. In making use of the porcelain boat this property was not lost sight of. No opportunity should be given for it to absorb any appreciable amount of moisture, as the dried boat need not be exposed to the moisture of the laboratory but a very short time while receiving the sample and being placed into the tube. Since the empty boat, which has been exposed to the air under conditions similar to those in the actual determination, is used in running the blank, a correction for the moisture which may be added this way is made when the blank is subtracted.

In the Cushman method (*Jour. Ind. & Eng. Chem.*, Vol. 3, p. 372) the statement is made that either platinum or silica

boats are used, and no reference whatever is made to the nickel boat which he now states is used.

Dr. Cushman's third and most important criticism is to the practice of weighing the phosphoric acid absorption tube filled with hydrogen. I consider the displacement of hydrogen by dry air as in the Cushman method unnecessary, since in drying the hydrogen filled absorption tube the same time is given and the same conditions maintained before weighing both before and after the combustion.

At various times experiments were conducted in order to determine whether or not the diffusion of hydrogen through the stoppers makes any variations in the weights which would materially affect the results. A phosphoric acid absorption tube was filled with dry hydrogen and dried over concentrated sulphuric acid for fifteen minutes before weighing, this procedure being repeated many times, and in no case was there any appreciable variation in weight. A second weight was made thirty minutes after the first in each case, and in no instance did the weight vary more than 0.0002 gram from the first, showing that, in a reasonable time limit, no appreciable error is introduced from this source.

R. H. McMILLEN.

Dr. Struthers' Reply

To the Editor of Metallurgical & Chemical Engineering:

Sir:—Enclosed please find a copy of a letter to me from Mr. Charles F. Rand, president of the American Institute of Mining Engineers, which is a conclusive reply to the direct and inferred criticisms, so far as they refer to me, appearing in the letter of Messrs. Corning and Stone in your issue of September, 1912.

I respectfully request, as a matter of justice, that you will publish this present communication and the letter from Mr. Rand in an early issue of your paper.

JOSEPH STRUTHERS.

New York City.

Mr. Rand's letter is as follows:

"Dr. Joseph Struthers, New York.

"Dear Sir:—Your letters of February 21 and 24 have been received, together with copies of the METALLURGICAL AND CHEMICAL ENGINEERING of September, 1912, the *Mining and Scientific Press* of January 25 and February 8, 1913, and the *Engineering and Mining Journal* of February 8, 1913, in which latter the suggestion is made that you demand an investigation; with the request on your part that the criticisms appearing in these publications as far as they relate to you should be considered by the Board of Directors or the Executive Committee of the Institute.

"Your letters and the accompanying newspapers have been carefully considered by the Executive Committee.

"We are very glad to state that no charges of any kind against you are in existence before the Board.

"Your accounts as Assistant Treasurer have been audited annually by a firm of certified public accountants and always found correct.

"As to the excursions which are specifically referred to by the *Mining and Scientific Press*, you are entitled to the statement which we very gladly make that you did not originate the system by which such excursions were conducted. The system had prevailed for many years, and before you became connected with the administrative work of the Institute.

"With regard to the reference in the *Mining and Scientific Press* to the New Haven and Spokane meetings, we now find that there was no excursion connected with the New Haven meeting, and understand that you had no financial relation beyond the receipt of salary and expenses to the excursion connected with the Spokane meeting. Both of these meetings were held while you were Assistant Secretary and before you became Secretary of the Institute.

"A committee of the Board and Council has already inquired

into the conduct of the excursion to Japan which was under your charge, and exonerated you, as shown in a report which has already been published.

"As to the letter of Messrs. Corning and Stone, published in METALLURGICAL AND CHEMICAL ENGINEERING last September, we appreciate the position taken by Dr. Raymond and you at the urgency of your friends, to abstain from any newspaper controversy which might have been harmful to the Institute. At the same time we are pleased to say, concerning the general charge which might be construed to include you, that you have not received an excessive salary and that you have not been inefficient in the office work.

"The Executive Committee consists of Charles F. Rand, Benj. B. Thayer, A. R. Ledoux, Joseph W. Richards, and James F. Kemp.

"Yours very truly,

"(Signed) CHARLES F. RAND,

"President American Institute of Mining Engineers."

Early American Mining Schools

To the Editor of Chemical & Metallurgical Engineering:

Sir:—On page 120 of the March number of your journal is a note on mining schools. In this the name of the School of Mining and Practical Geology of Harvard University is omitted. This school was founded in 1865 by the appointment of Prof. J. D. Whitney to the chair of geology in 1865. In 1866 Prof. R. Pumpelly was appointed to the chair of mining, and in 1871 William H. Pettee, who had been acting as instructor, was appointed Assistant Professor of Mining.

The first class of four members was graduated in 1870. Two of these Gannett and Marvin, entered the United States Geological Survey, where Gannett still remains. In 1870 the class was taken to Michigan by Professor Pumpelly to see the iron and copper mines, and afterwards J. D. Whitney took them to the mountains of Colorado. During this part of the trip Mt. Harvard and Mt. Yale were ascended and named.

This party, so far as I know, was the first college party to make a summer visit to the Rocky Mountains. The party consisted of Prof. J. D. Whitney, of Harvard; Prof. William Brewer, of Yale; Instructors Pettee and Sharples, of Harvard, and four students, William M. Davis, who has succeeded Professor Whitney as geologist at Harvard; Joseph Bridge, Henry Gannett, now chief geographer of the United States, and A. Marvin, who was on the United States Survey, but died in 1876. Mr. Bowles, son of the editor of the *Springfield Republican* was also with the party. They were also accompanied by Charles Frederick Hoffman as topographical engineer. The school was discontinued in 1875, being merged with the Lawrence Scientific School.

Boston, Mass.

S. P. SHARPLES

The Solubility of Alumina in a Bath of Fused Fluorides.

To the Editor of Metallurgical & Chemical Engineering

Sir:—In the March number of your journal, page 121, Dr. Charles A. Doremus discloses from a paper published by St. Claire Deville in 1857, that alumina like silica was known to be soluble in a mixture of potassium and sodium fluorides fused in an externally heated crucible; and that while Deville succeeded in electrolytically depositing silicium by feeding silica into such a bath, he failed to deposit aluminium under the same conditions. Deville's conclusion was that alumina unlike silica, is not decomposed by the alkali metals.

Dr. Doremus stated that had Deville's proportions been more propitious the alumina should have been decomposed by the electric current in the same manner as silica. Deville's bath contained no aluminium fluoride. This latter deduction made by Dr. Doremus would be natural if he considers alumina when fused an electrolyte whose molecules are directly decomposed without a secondary reaction. The old literature of electrolysis teaches that pure oxides like water are not directly decomposed by the current. Deville was expecting that the liberation of

potassium or sodium on the cathode would react on alumina in the bath with the formation of aluminium, while at the same time oxygen or carbonic oxide would form against this carbon anode and fluorine would have an opportunity to combine with the alkali metal of the alkali oxide that would be forming in the bath. He knew that an alkali metal would reduce silica.

Dr. Paul Héroult in his patents and the experts for Mr. Charles M. Hall in litigation that was never decided all held that alumina in itself was capable of being directly decomposed by electrolysis. In the latter case the experts for the Cowles Electric Smelting & Aluminum Company held that it was well known that alumina was soluble in cryolite, but that alumina was not a direct electrolyte.

The following experiment performed by the writer about twenty years ago must have some scientific bearing on this subject:

A round hard carbon block, 3 in. in diameter and about 3 in. in height, was taken. Three holes were bored into one of the flat surfaces of this block to a depth of about an inch and of nearly the same diameter. One of these holes was filled with pure sodium fluoride NaF, another was filled with cryolite $(\text{NaF})_2\text{Al}_2\text{F}_6$, and the third was filled with cryolite containing a little added aluminium fluoride. The block was now uniformly heated until the material in all three holes came to quiet fusion. Three small pieces of aluminium, all having the same weight, had been previously prepared each about the size of a small bean. One of these pieces was now dropped into each of the three fused baths. The bath of sodium fluoride gave off a great abundance of sodium vapor which burned with its characteristic yellow flame. The bath formed of cryolite gave off some yellow flashes of sodium vapor. The bath containing a slight excess of aluminium fluoride, above that of cryolite, gave off no sodium vapor. Upon allowing the block to cool and breaking it, it was found that all the aluminium had been consumed with the formation of aluminium fluoride in the bath formed of sodium fluoride. On weighing the button from the cryolite bath, it was found to have lost a very small per cent of its weight, while the bath containing a slight excess of aluminium fluoride gave up a button having its original weight.

Dr. Percy in the year 1855, and Rose independently in 1856 discovered that cryolite could be directly reduced and aluminium produced by using sodium as a reducing agent, but they found the efficiency very low. This was due to too great a quantity of sodium fluoride accumulating in virtue of the reduction of the aluminium fluoride with sodium.

All three baths were heated to the same temperature in the above described experiment, which was about the temperature employed in the present commercial manufacture of aluminium. It will be noted that when aluminium fluoride is in excess to that contained in cryolite $(\text{NaF})_2\text{Al}_2\text{F}_6$, aluminium does not reduce sodium fluoride, and on the other hand, when sodium fluoride is in excess, aluminium does reduce sodium fluoride, and sodium acts in just the reverse manner as to aluminium fluoride in the composition.

Déville might have said at his time that aluminium and sodium reverse their positions in the electropositive and negative series in these different mixtures, but modern chemists, I think, would explain this as a phenomenon of mass action, but it still leaves open the question as to whether alumina in a pure condition is or is not like water a non-electrolyte.

ALFRED H. COWLES

Seawaren, V. J.

New Mill at Manhattan, Nevada

The amalgamation mill of the Big Four company, at Manhattan, Nevada, was put in operation early in March. While this is a small mill, it is well equipped with modern machinery, and its operation is regarded as an important event in the history of Manhattan. The ore is free-milling. It is first crushed in a gyratory crusher, then in stamps. The stamp product is classified into sand and slime by Akins classifiers, the sand being reground in tube mills. Amalgamation follows tube milling. The capacity will be 120 tons per day.

Atlantic City Meeting of American Electrochemical Society

The spring meeting of the American Electrochemical Society will be held in Atlantic City from April 3 to 5 (Thursday to Saturday of the first week of April). Headquarters will be at the Hotel Traymore, and the professional sessions for the reading of papers will be held at the Solarium at the hotel.

Thursday and Saturday will be completely devoted to reading and discussion of papers, while on Friday, April 4, an excursion will be made to Philadelphia, leaving Atlantic City on the Pennsylvania Railroad in a special car attached to the 7:45 a. m. train and arriving at Broad Street station at 9:10 o'clock. The works of the Crucible Steel Castings Company at Lansdowne, Pa., will be visited in the morning where the making of crucible steel will be seen and a 2-ton Roechling-Rodenhauser induction steel furnace will be inspected.

At noon the party will return to Philadelphia and a visit will be paid to the University of Pennsylvania, where Dr. Edgar F. Smith, the provost of the University, will address the society.

After lunch visits will be paid to the Harrison Bros. Company on the Grays Ferry Road (leads, paint, lithophone, contact sulphuric acid) and to the United Gas Company Works at Point Breeze (water gas, illuminating gas, and gas testing laboratories).

The party will return to Atlantic City, leaving Broad Street station at 4:14, arriving at Atlantic City at 5:39 p. m. On the evening of Friday, after the lecture by Professor Kenrick, a smoker will be held at a place to be announced at the meeting.

The program of papers is as follows:

Thursday, April 3, 1913

10:30 a. m. Annual business meeting of the society, in the Solarium, of the Hotel Traymore; reports of the Board of Directors; announcement of the annual election; miscellaneous business.

The following papers will then be read and discussed:

Conduction and radiation of heat, by *J. Langmuir*.

Experiments with furnace electrodes, by *F. A. J. Fitzgerald* and *A. T. Hinckley*.

Aluminium nitride, by *J. W. Richards*.

Some tests of the Edison Storage Battery, by *C. W. Bennett* and *H. N. Gilbert*.

Concentration cells containing organic liquids immiscible with water, by *R. Beutner*.

Concentration changes in Copper Sulphate Electrolysis, by *C. W. Bennett* and *C. O. Brown*.

The 3-phase, 2-phase induction furnace, by *A. E. Greene*.

Making Electric Steel without Slag, by *A. E. Greene*.

On Friday, April 4, 1913, a lecture will be given in the Solarium, Hotel Traymore, by Prof. Frank B. Kenrick, of Toronto, on the subject of hyperphasia.

Saturday, April 5, 1913

10:30 a. m. Presidential address by President *W. Lash Miller*, introducing the symposium on the electrodeposition of metals.

Symposium on Electrodeposition of Metals:

Electrodeposition of Gold and Silver, by *Francis C. Frary*.

Electrodeposition of Copper, by *C. W. Bennett*.

Electrodeposition of Brass and Bronze, by *C. W. Bennett*.

2:30 p. m.

Electrodeposition of Cobalt and Nickel, by *O. P. Watts*.

Electrodeposition of Lead, by *F. C. Mathers*.

Solid thick lead cathodes from lead lactate solutions, by *F. C. Mathers* and *W. B. Cockrum*.

Registration will begin on the evening of Wednesday, April 2, in the lobby of the Hotel Traymore, and a meeting of the Board of Directors will be held on the same evening at 8:30 p. m.

Dr. W. Lash Miller of the University of Toronto, is the president of the American Electrochemical Society. Dr. J. W. Richards of Lehigh University, South Bethlehem, Pa., is the secretary.

Annual Meeting of the British Institute of Metals

Abstracts of Papers Presented

The annual general meeting of the (British) Institute of Metals was held in London on March 11 and 12.

The report of the Council states that the year 1912 has marked a period of material development in the activities of the Institute. The number of members is 614.

Corrosion Committee

From the report of the corrosion committee we note that considerable progress has been made in the investigations of the causes of corrosion of tubes of the four types of alloy selected by the committee, namely, 70:30 brass, Admiralty mixture, lead-bearing brass, and Muntz metal. Twelve tubes of each alloy have been tested in the special condenser plant for nine months, *i. e.*, from April to December, 1912. Three tubes of each composition have been withdrawn for detailed examination; this, however, has not yet been completed. A preliminary examination has shown that a small amount of corrosion such as that usually met with in tubes that have failed in practice, has occurred in some of these tubes, but has not penetrated to any considerable depth. All the tubes have been found to be covered with a scale of composition similar to that typical of those used in the mercantile marine. Investigation on these tubes is still proceeding.

The plant itself was closed down temporarily on Dec. 31, 1912, pending the supply of further funds for working expenses which amount to about £100 per annum. It is highly desirable that the experiments with this plant should be continued at the earliest opportunity, and this will be done as soon as the necessary funds are forthcoming.

An extensive scheme of laboratory experiments has been devised with the object of elucidating the nature of reactions which take place during the processes of corrosion and scale formation. It has been found necessary to continue a number of experiments for periods of several months, as the collection of data is necessarily slow. Hitherto it has not been possible to devise any satisfactory "acceleration" test, so work in this direction has been abandoned for the present.

A considerable number of badly corroded tubes have been sent in for examination by various shipping firms and manufacturers, and afforded useful information. The investigator is now desirous of obtaining a number of tubes that have endured exceptionally long service in marine or land condensers.

In the following we give abstracts of the papers presented at the meeting:

Metallic Filament Lamps

A paper on "Metal Filament Lamps," by Mr. Alexander Siemens, summarizes the history of the use of metallic filaments in glowlamps.

Owing to the uneconomical working of carbon-filament lamps, endeavors were made to replace carbon by one of the rarer metals, which can sustain a higher temperature than carbon without disintegrating.

Auer was the first to utilize osmium, prepared by a squirting process, and his methods were followed by several other inventors experimenting with various metals.

The first lamp to have actually drawn metal wire as its filament was the tantalum lamp manufactured by Siemens & Halske, Berlin. They also succeeded in drawing an alloy of tungsten and nickel, but before that process was perfected the General Electric Company, of Schenectady, patented a process to make pure tungsten ductile, which is described in the paper.

Corrosion of Condensed Tubes

A paper by Mr. Arnold Philips deals with "The Corrosion of Distilling Condenser Tubes."

Main and auxiliary condenser tubes become corroded on the sea water side; corrosion on the steam side of the tubes practically never occurs.

In distilling condensers the reverse of this is the case. No

corrosion occurs as a rule on the sea water side of the tubes but frequently occurs on the surfaces exposed to the steam.

The absence of corrosion of the sea water side in distilling condensers is apparently due to the facts that (1) the sea water flows outside the tubes, which tubes are generally placed vertically; on this account no particles of carbon, ash, etc., can find a lodgment on the surface of the tubes on the sea water side and thus what the author has shown to be one of the most important causes of corrosion is absent. (2) The tubes are usually in direct metallic connection with the casing, being expanded directly into the tube plates; this permits the full galvanic protective effect of any protector bars and of the casing itself when this is wholly or partially of iron or steel.

The corrosion on the steam side of distilling condenser tubes is due to hydrochloric acid in the steam.

The origin of the hydrochloric acid is the dissociation of salts contained in sea water, probably magnesium chloride. This dissociation only takes place to any noticeable extent when the primary steam tubes in the evaporators project above the surface of the brine which is being boiled.

The same distilling condenser used with two evaporators, one of which has steam coils projecting above the brine surface and the other having drowned steam coils, produces distilled water containing hydrochloric acid in the former case, but free from this acid in the latter case.

The effect of the acid-containing steam from the evaporator is to corrode the surface of the distilling condenser tubes and the distilled water obtained contains not only free acid but also chlorides of copper, zinc, and (if tin-coated tubes are used) also tin.

The presence of copper in the distilled water is particularly objectionable both for potable uses and also because when passing into the boilers it tends to set up further corrosion and pitting on the steel surfaces.

The cure to avoid these troubles is to use distiller evaporators which contain completely drowned coils. A palliative to prevent copper passing into the boilers with the distilled make-up water, if this contains copper due to a faulty form of evaporator being used, is to pass the distilled water through a zinc scrubber which removes the copper.

Chemical methods for detecting and measuring minute amounts of free hydrochloric acid in the distilled water obtained from distilling condensers are described.

Corrosion of Aluminium

A paper by Dr. G. H. Bailey deals essentially with the action of water and salt solutions on aluminium.

In the course of the investigation the effects of variation in the nature of the waters used and in the concentrations of the salt solutions have been examined. A large number of results are given illustrating also the dependence of corrosion on temperature and on the quality of the aluminium employed.

The author also gives a method by which reliable measurements of the rate of corrosion may be made, and from an examination of the experimental evidence he draws the following conclusions:

That aluminium of high purity is less readily acted upon than that of lower purity and that the presence of sodium and copper in the metal increase the rapidity of corrosion. Well-annealed metal is also more resistant to corrosion than unannealed metal. He finds that in general the corrosion of aluminium is a process of oxidation, and that as a matter of fact metal exposed for several months to water or salt solutions from which the dissolved air has been expelled underwent no corrosion whatever. The normal course of corrosion (excluding the action of acids and alkalis) is thus a transformation of aluminium into alumina, which separates out as a flocculent precipitate without any of the aluminium passing into solution.

Microstructure of German Silver

A paper by Mr. O. F. Hudson deals with the microstructure of German silver. Samples of German silver which had been annealed for varying lengths of time at a temperature of

7000 deg. C. were examined microscopically. The alloys which consist of a single solid solution, require many hours annealing at this temperature to bring them to a condition of true equilibrium when the solid solution appears to be perfectly homogeneous. German silvers when annealed thus commonly possess a characteristic "cored" structure which is independent of the normal twinned crystalline structure also seen.

The rather coarsely crystalline structure which results from the long annealing necessary to remove the "cores" is not in itself a sign of deterioration in rolling qualities. The results of tests on samples annealed for various times at temperatures up to 1000 deg. C. showed that, under laboratory conditions, the rolling qualities of good German silver are not impaired by severe annealing.

Hardness tests, using the scleroscope, showed that prolonged annealing, accompanied by pronounced crystal growth, does not lead to any decrease in hardness beyond that due to the normal annealing operation.

Effect of Rapid Cooling on Constitution

A paper by Mr. G. H. Gulliver deals with "the quantitative effect of rapid cooling upon the constitution of binary alloys."

The author shows how to calculate the proportions of the constituents of a rapidly cooled binary alloy by means of the information obtained in the usual manner from very slowly cooled alloys. The importance of the subject is due to the fact that the constitution of a cast alloy cooled at ordinary rates lies between that of the very slowly cooled and that of the very quickly cooled mixture, so that its limits of variation with change in the rate of cooling can be now specified.

The method of calculation is applied to the lead-rich alloys of the lead-tin series. The proportion of eutectic in a just solid alloy, the proportion of liquid and of solid in an alloy at a temperature between its freezing and melting points, and the rate of solidification of an alloy at a given temperature, when slowly and when rapidly cooled, are found numerically. The apparent form of solidus obtained from a rapidly cooled alloy is given, together with the variation in the apparent position of the saturation point which accompanies variation in the rate of cooling. It is shown that the position of the apparent saturation point depends not only upon the rate of cooling, but still more upon the composition of the alloy, and further that the proportion of eutectic present in a rapidly cooled alloy is sensibly independent of the curvature of liquidus or solidus.

The paper is accompanied by a number of diagrams which clearly show the differences between the conditions which prevail during slow and rapid cooling respectively.

Heat Treatment of Gun Metal

A paper by Messrs. H. S. Primrose and J. S. Glen Primrose deals with the "practical heat treatment of Admiralty gun metal."

As difficulties often arise in producing gun-metal castings to fulfil specified physical tests and withstand hydraulic pressure, the authors describe their experimental work with the object of finding a simple and reliable method of improving this commonly used industrial alloy so as to obtain the highest possible strength and elongation accompanied by greater soundness and homogeneity of the metal. They found that even in the absence of blowholes, which constitute the commonest source of unsoundness, cast gun metal behaves unsatisfactorily under hydraulic tests due to the presence of microscopical pores formed between two constituents of widely different properties.

A series of tests was carried out to investigate the practical value of various kinds of heat treatment, such as reheating, quenching, and annealing test bars of gun metal conforming to the Admiralty specification of 88-10-2, which had been cast in sand and chill molds and then cooled at different rates. The sets of normal and treated bars were tested physically and examined microscopically to determine exactly the effect of quenching from different temperatures and also of annealing for various periods of time at different temperatures.

The first set of tests made showed no improvement was

effected by reheating and quenching the bars, as the strength and elongation fell off rapidly as the temperature was raised. This result was unexpected as it is known that pure bronze is increased in strength by similar treatment.

More satisfactory results were obtained by simply annealing the metal at various temperatures, followed by moderately slow cooling, as this was found to considerably increase both the tensile strength and the elongation. The most marked improvement was found to be produced by annealing the bars for half an hour at a temperature of 700 deg. C., as the physical tests showed lower results both above and below this critical point. The time factor was also investigated and found to be critical for the $\frac{5}{16}$ in. thickness of metal used at thirty minutes, although only a slight improvement resulted after annealing for twenty minutes, and a slight diminution in strength occurred if annealing was too long prolonged.

The practical applications were discussed and examples quoted from practice in which material not otherwise defective failed under the hydraulic test due to water sweating through the microscopic pores, but after suitable annealing conformed to the most rigid tests. The increased homogeneity of the metal after the heat treatment was shown to be due to the absence of eutectic segregations from the microstructure, leaving only the strongly interlocking crystals of alpha solid solution of the tin and zinc in the copper. It was anticipated that this heat treatment would minimize corrosion troubles.

The headquarters of the Institute of Metals are at the Caxton House, Westminster, S. W., London. Mr. G. Shaw Scott is the secretary.

The Non-Ferrous Metal Market

No marked changes have occurred since our last report. Business has been fairly quiet, and the quotations were not realized on all transactions. At the latest reports the different markets have assumed a firmer tone, and it is expected that this condition will continue.

Copper.—The domestic market has been quiet and few purchases have been made. Most of the business has been effected at concessions under the quoted price. The bulk of the sales have been made to foreign buyers who have been attracted by the prevailing low prices. Little Lake Copper has been sold, and the market has not yet been firmly established on a 15-cent basis. The last quotations are 14 $\frac{3}{4}$ @15 cents for Lake, and 14.70@14.80 cents for electrolytic.

Tin.—Wide fluctuations have been noticeable in the London market, but have not been reflected in this market. The favorable February statistics gave a firmer tone to the March market, and liberal purchases were made, especially for future delivery. The latest quotation is about 48 $\frac{3}{4}$ cents, New York.

Lead.—A firmer undertone has prevailed in this market and sales have been heavier. The market is active at 4 17 $\frac{1}{2}$ @4.20 cents, St. Louis, and 4.32 $\frac{1}{2}$ @4.35 cents, New York.

Spelter.—Prices have advanced a little under the effect of a better inquiry for metal. Quotations have a wide range according to delivery, the last being 6.05@6.15 cents, St. Louis, and 6.20@6.30 cents, New York.

Other Metals.—Aluminum has shown a firmer tone since our last report, being quoted at 26@27 cents, New York. No material change is noted in the antimony market, prices ranging from 8 $\frac{1}{4}$ to 9 $\frac{1}{2}$ cents for various brands. The quicksilver market is quiet; the New York quotations being \$40 per flask of 75 lb. The San Francisco price is the same, except for export, the latter being \$37.50.

Nissen stamps have become popular machines for crushing ore in Rhodesia, where three new mills are being equipped with these machines. Roasting also is a feature in several of the new Rhodesian mills.

Tilting Crucible Melting Furnaces for aluminium, brass, bronze, copper, gold, silver and other non-ferrous metals are the subject of illustrated catalog 44 of the W. S. Rockwell Company, of New York City.

Evolution of Methods of Handling Slime—I

By H. N. Spicer

Modern methods of handling ore-slime, either in concentration or cyanidation, are comparatively recent developments in the history of metallurgy. It is necessary only to review the literature on this subject for the past decade to find that slime has been the source of much trouble, and that its successful treatment has been the subject of many investigations and inventions. The result is a comparatively high state of develop-

FIG. 1.—REMOVING SAND FROM COLLECTORS AT NUNDYDROOG MINE

ment in the art of handling this once troublesome material, and the successful extraction of valuable metals from it.

The methods employed in classifying, thickening, agitating and filtering slime probably are matters of common knowledge to well informed engineers; but it may be surprising to many to learn of the crude yet profitable methods employed in those countries where the latest mechanical appliances are not yet in use. The writer visited last year some of the important mining districts of the world, and being specially interested in the slime problem, took many notes and interesting photographs on the prevailing methods in the different countries. In India, as in many other foreign countries where nature labor is employed, the methods of operation may appear crude to the uninitiated; but it must be borne in mind that these methods have been determined by the prevailing labor conditions, and that those in authority deserve much credit for determining the economic limit to which this class of labor can be used.

Methods in Vogue in India

India at this time presents a particularly interesting phase of the slime problem, because the industry is in the midst of a period of transition from the old to the new. Prevailing methods of handling slime probably are the crudest to be seen anywhere in the world; and yet it will be but a short time until they are wholly abandoned in favor of modern methods. Already there is some evidence that the old order of things has

FIG. 2.—REMOVAL OF SLIME FROM COLLECTING TANK AT NUNDYDROOG MINE

passed, and that the strange operations shown in some of the accompanying illustrations will no longer be seen.

Gold mining has been a profitable industry in India for many years, but it is only within the last year that the first slime-treatment plant was erected. Prior to that time some sand had been leached with cyanide solution, but only such slime was treated as might remain with the sand and still give a

leachable product. The consequence is that large tonnages of slime await treatment at the different mines. It is probable also that a large portion of the leached sand is sufficiently valuable to be reground in tube mills and treated as slime.

The principal reason why so little attention has been paid to cyanidation in India is that the gold recovery by amalgamation has been so efficient. In the Mysore district, for example, from 82 per cent to 85 per cent of the gold in the ore is recovered by stamp-amalgamation. The sand and slime represent a value worth recovering, however, and they are being saved with that end in view; but now that cyanidation is about to be widely adopted, the slime problem is complicated by the fact that the ore is crushed in water, necessitating the dewatering of both sand and slime before further treatment.

The mill at the Balaghat mine, on the Kolar gold field, Mysore, is a very old one. The pulp from the stamps runs into concrete pits in the ground; the slime and water overflow, and when the pit is full of sand it is excavated by hand and stacked for future treatment. The slime flows to other concrete tanks, where the pulp is thickened by free settling to about 50 per cent moisture and then excavated and stacked by hand.

Sand and Slime at Nundydroog

Methods of dewatering at the Nundydroog mine represent a step in advance of those at the Balaghat; they are shown in

FIG. 3.—ELFVING SLIME FROM THICKENING TANKS AT NUNDYDROOG

Figs. 1, 2, 3 and 4. The stamp-mill pulp flows to steel collecting-tanks, which are equipped with Butters distributors, as shown in Fig. 1. When a tank has been filled, the flow of pulp is diverted and the sand allowed to drain. It is then dug out by hand, the work being done for the most part by women using a kind of hoe and a small wicker basket. Stacks of old tailings may be seen in the background.

The slime overflowing these sand collecting tanks passes through launders to a series of concrete settling basins, shown in Fig. 2. Here the slime settles to a consistency of about 55 per cent solids, after which it is elevated and stacked by means of a native contrivance known as a "deckool." Its operation will be better understood by reference to Figs. 2, 3 and 4. In Fig. 2 the bucket is shown lowered to the woman in the slime pond, who fills it, after which it is elevated as shown in Fig. 3 to a man who dumps it into a launder, Fig. 4. As most of the slime is too thick to run in any launder, it is pushed or scraped along to the dumping place by women provided with implements for the purpose.

The Ooregaum 80-stamp mill is shown in Fig. 5. At this

point reference may be made to the construction of mill and other mine buildings in the Mysore district, which are built of dressed granite, with walls 3 ft. thick. To one unfamiliar with local conditions, this must appear to be an extravagance; but as a matter of fact, the cost of this type of construction is less than for frame and corrugated iron.

The stamp batteries are arranged in two sets, facing each

FIG. 4.—DUMPING SLIME INTO LAUNDER, NUNDYDROOG MINE

other, and the combined pulp flows out at one end of the mill. Formerly the sand was allowed to settle in pits with walls of masonry, as shown in Fig. 6, the slime overflowing to settling basins. Later this was abandoned and the pulp conveyed in an open launder to a series of steel sand collecting-tanks, shown in the middle background of Fig. 7. At the head of the open launder are two spitzluten, by means of which from 10 per cent to 12 per cent of the coarsest sand is eliminated for future

FIG. 5.—OOREGAUM 80-STAMP MILL

regrinding. It falls to the ground and is taken to a dump by women, who fill the cars as shown in Fig. 6.

The remainder of the sand and slime passes on, as above indicated, to steel sand-collectors, Fig. 7, the slime overflowing to the concrete slime pits in the foreground. These pits have pyramidal bottoms, and are approximately 35 ft. square at the top, and 16 ft. deep in the center. Formerly the thickened slime

was pumped to the dump, but since the installation of a 30-leaf Butters filter the procedure is as follows: The slime is allowed to settle as much as possible and the supernatant water is pumped off by means of a portable pump shown on a truck at the right of the settlers. Cyanide solution is now added in quantity to give a pulp containing about two parts of solution to one of solids. Compressed air is turned into the pulp from the pipes shown extending from the left side to the center of the settlers. This agitation keeps the solids in suspension while the pulp is being pumped to a series of four 19 ft. by 10

FIG. 6.—ELIMINATION OF THE COARSE SAND AT OOREGAUM MILL

ft. Pauchuca agitators. After agitation the pulp is filtered in a Butters filter, shown in Fig. 8. This illustration is particularly interesting as affording a view of the first vacuum filtration plant erected in India. The filter builds a cake of about 1 1/16 in.; the cycle of filtration, washing and discharge occupies from 50 to 60 minutes.

Sand and Slime Separation at the Mysore Mine

At the Mysore gold mine, sand and slime are separated by the system shown in Fig. 9. The stamp mills are out of view at the right. The battery pulp flows through the launder shown supported on a trestle at the farther end of the row of tanks, and thence into two transverse launders built of masonry. Pipes leading from these transverse launders deliver the pulp

FIG. 7.—THICKENING SLIME AT OOREGAUM MILL

to Butters distributors placed over two rows of filter-bottom steel tanks. Only one row of tanks is shown in the view, the other being at the left. Each tank is provided with an overflow launder for slime, which passes to a series of concrete settling basins where it is handled in the same manner as at Nundydroog, as shown in Figs. 2, 3 and 4.

When a tank has been filled with sand, the feed is discontinued and the charge drained as dry as possible by vacuum applied under the filter-bottom. Naturally this system of separating sand and slime is not the most efficient, particularly in the be-

ginning of the operation when the tank is empty. The consequence is that the lower part of the charge contains more or less slime which affects the uniformity of drainage and leaves a variable quantity of moisture in the sand. After draining the charge as dry as possible it is discharged by hand through doors in the bottom of the tank, falling onto belt conveyors, which transport it to the dump shown in the hack-

FIG. 8.—PACHUCA AGITATORS AND BUTTERS FILTER AT OOREGUM MILL

ground. Extensive experiments are now being carried out to determine the best type of cyanide plant to build for the treatment of this ore.

First Complete Slime Plant in India

The first complete slime-treatment plant in India has been built at the Champion Reef. Fig. 10 shows the Champion Reef 180-stamp mill, with slime settlers and Pachuca tanks at the right. The battery pulp flows over plates and then to cone classifiers, the slimy overflow from which gravitates to two 50 ft. by 8 ft. slime-collecting tanks, which have 4-ft. conical bottoms, and in which the slime is thickened to a consistency of about 55 per cent solids. After decanting the water the slime is sluiced out with cyanide solution, and pumped to three 33 ft. by 10 ft. Pachuca tanks connected in series. Vacuum filtration completes the treatment.

Transition to Modern Methods

Turning now from past operations to present and future

FIG. 9.—SAND COLLECTORS AND CONVEYORS AT MYSORE GOLD MINE

plans, we find many instances of the transition to modern methods of handling slime. At Nundydroog a slime plant was designed last year and is now being erected. It comprises eight Dorr thickener classifiers, four tube mills, three 30 ft. by 10 ft. Dorr thickeners, four 38 ft. by 10 ft. Pachuca agitators and a 120-leaf Butters filter. At Ooregum the old clumsy method

of thickening the slime is to be replaced by Dorr thickeners. At Mysore experimental work is under way to ascertain what proportion of the ore should be treated as slime in an up-to-date plant. In all probability tube mills will be used, as well as the latest developments in mechanical classifiers, thickeners, and vacuum filters.

At the Jubtil mines of Anantapur, in the Madras Presidency, 60 miles north of the Kolar field, a 20-stamp mill is about completed which will be the first in India to adopt crushing in cyanide solution. This will greatly simplify the slime problem by eliminating the necessity for dewatering. The equipment includes stamps, amalgamating-plates, tube mills, Dorr thickeners, Pachuca agitating-tanks and Butters filter.

Near Raichur, in the native state of Hyderabad in the Deccan, is an old gold mine known as the Hutti (Nizam). It has

FIG. 10.—CHAMPION REEF 180-STAMP MILL, PACHUCA TANKS AT RIGHT

been operated intermittently for many years, the sand and slime being handled in as crude a way as in the old plants of the Mysore district. A modern mill is now being erected, to treat about 70 tons of ore per day, using a tube mill, Dorr thickener, and small Butters filter.

Throughout India the process of evolution in gold metallurgy, particularly in the treatment of sand and slime by cyanidation is very noticeable, and within a year or two the old ideas and methods will have been completely abandoned.

Denver, Colo.

Advantages of Small High Speed Electric Furnaces.

By Carl Hering

The question is often asked how much electric energy will be required to melt a specified amount of metal in a foundry for casting purposes. It is not generally understood, however, that to answer this question intelligently and to the satisfaction of the proposed user, there are other factors which one should also know as they may have an important bearing on the result. For instance, a small furnace which melts many small charges per day, and a large one which melts only a few large charges per day, can have the same daily output, and yet may require quite different amounts of electrical energy, hence different amounts per pound. The amount of energy required may also be materially different depending upon whether a given quantity of metal is melted rapidly or slowly.

The purpose of the present article is to analyze and discuss these two features of electrical furnaces, to show their significance and importance, and to illustrate the results with some estimated approximate quantitative data.

The user of a commercial furnace is not interested in theoretical efficiencies or in the so-called radiation losses, electrode losses, etc.; the efficiency which he is interested in is the amount of product produced per dollar; this may be represented by the simple formula $P/\$$, in which P is the amount of the product produced, and $\$$ is the total cost of producing that amount; the greater this "efficiency" the better he is pleased. Hence the duty of the engineer is to do everything and anything to increase this commercial efficiency, even though this may include some things which by themselves might appear to be bad practice because they are inefficient; if they increase this commercial efficiency they become good practice.

Some years ago the writer made the statement that the most efficient electric furnace is the electric fuse for protecting electric circuits when it "blows out" on a short circuit. Its efficiency, as a furnace, for sudden short-circuit currents, is probably high in the nineties, that is, very nearly perfect. The reason for this is that the heat is generated so rapidly that the metal is melted, and the intended process is completed, before any appreciable amount of the heat has had time to get lost.

This little "furnace," therefore, teaches us the importance of proceeding as quickly as possible not only in generating the heat, but also in doing whatever is to be done with the metal while it is melted, such as casting it, purifying it, mixing alloys, etc.; in other words, *to reduce as much as practicable the time during which each pound of metal must be kept hot*. During the whole of that time it is losing heat, and this "stand-by loss" increases in proportion to this time; hence if the melted metal can be melted and handled twice as quickly, this loss will be approximately halved. And as these stand-by losses are by no means small and insignificant, their reduction becomes important.

There are in general two ways in which these "time" losses in electrical furnaces can be reduced in practice. The first is to get the heat into the metal as quickly as practicable, that is, to force the furnace to the greatest practicable extent. This means to increase the power delivered to the furnace (the kilowatts, not the kilowatt hours) as much as practicable, and to get this energy into the metal as quickly as possible; in those resistance furnaces in which the heat is set free in the metal itself, absolute perfection has been reached in not losing any time in getting the heat into the metal after the heat has been generated, as it gets there instantaneously; in arc and other furnaces depending chiefly upon radiation and conduction it will necessarily take some time for the heat to get disseminated in the bath, and it is difficult to see how that time can be reduced except by very high temperatures and by rapid circulation. Furnaces which can be forced are, therefore, better in this respect than those which cannot.

The second way to reduce these stand-by "time" losses is to reduce the quantity of metal which forms one charge, to the smallest amount that the particular conditions warrant, so that the heated charge may be disposed of as quickly as practicable, thereby reducing the time that each pound of metal is losing heat. For instance, if the purpose is to cast into molder's flasks taking, say, 50 pounds each, then the ideal furnace would be one which melted a charge of about 50 pounds at a time; the losses in such a furnace would be less than in one which contained a charge of 100 pounds, as the latter has to hold the charge twice as long. Hence the size of the charge must be decided by the user, but his attention should be called to the possible economy of the smaller charges, as it would probably not suggest itself to the average foundryman; in fact, he would probably have difficulty in understanding it even after it was explained to him, as the best electric furnace practice differs from the customary fuel furnace practice.

In some cases it is important to have large charges, as, for instance, when an alloy of very definite proportions is required; it may be too troublesome to mix small batches, especially when samples have to be analyzed. Also when slag must be changed. A certain amount of time may also be necessary in certain refining operations. In all such cases the conditions govern what should be done. But even in such cases one should bear the above in mind and make the charges as small and the time of heating as rapid as the particular conditions permit, if economy of energy and the reduction in the size of the furnace are important.

By thus reducing the charges to the smallest which are practicable, and melting as quickly as possible, the size of the furnace may be greatly reduced, so much so that it may be possible in some cases to make it portable either on rails or suspended from an overhead track, thus enabling it to be brought to the flasks or other molds in a foundry, thereby permitting casting directly from the furnace into the molds; this not only

saves some of the superheat, probably a very appreciable amount, but it also saves labor, pouring ladles, heating the latter, etc. It may also make it practicable to enclose the whole furnace in a closed tank for heating in a vacuum or under pressure, for refining.

The ideal plant for a foundry, for instance, where regular work is done, would be a furnace which contained only about as many pounds of metal as are cast into one flask, and which melted this much metal in the time it takes to move the furnace from one flask to another and to do the pouring. For small brass castings, such a furnace would be small enough to be readily handled on a track or suspended from a trolley rail, and could be tilted so as to cast directly into the flasks. Such a furnace is now under construction for a brass foundry, though it was not considered wise to go to the extreme of the ideal; in the present case, for instance, the furnace will contain enough metal for several flasks.

It is by making use of every possible advantage of the properties of the electric furnace in ways like these that the greater cost of the source of heat may be more than overbalanced by other gains of money value.

Elsewhere the writer has shown¹ that the losses through the walls are in general greater per pound of metal, for small than for large furnaces, and that, therefore, furnaces should better be built of large capacity; yet the arguments given above seem to lead to opposite conclusions; the facts are that both conclusions are right when properly interpreted (see Figs. 1, 2 and 3 in the concluding summary).

In general small machines are not as efficient as large ones, and yet from what was said above the contrary is true about furnaces. Again, a machine which is forced or overloaded is in general running less efficiently, and yet the contrary is here claimed to be the case for furnaces.

These apparent inconsistencies are due to the fact that with furnaces there are so many different factors involved which affect the result in different and sometimes contrary ways, that the problem sometimes becomes quite confusing. The only satisfactory way to study them is to determine the laws governing each

factor alone and then in various combinations. The writer has published at various times analyses and discussions of the laws of the losses through the walls, and those through the electrodes; in the present article the effect which the element "time," or speed of operation, has upon the losses is discussed with the other two sources of losses.

When problems become complicated because there are so many variable factors, it is often instructive and helpful to study extreme cases. In the present instance time or speed is the chief element under discussion; it appears that the greater the operating "speed" of a furnace the more economical it will be; imagine therefore a furnace in which this factor is carried to its extreme limit. Such an imaginary furnace is shown in outline in the adjoining sketch. Let B be a small block of refractory material with a very small U-shaped hole through it, and with the electrodes EE attached to a source of current. Let M be the mold into which the melted metal is to be cast and let WW be reels of wire of that metal capable of being fed rapidly into the holes. The current through the metal in the holes heats and melts it, and the melted metal immediately runs into the mold. Suppose the wires to be fed in as fast as the melted metal can flow out, and suppose the electric current supplies energy fast enough to do the melting at this rate and that the "pinch effect" did not interfere.

¹Heat Conductances Through Walls of Furnaces. Trans. Amer. Electrochem. Soc., Vol. 14, p. 225 (1908).

It will be seen that this would be an extremely small and highly efficient furnace; it would probably have the highest possible efficiency of any electric furnace, the reason being that the metal is melted and discharged into the mold so rapidly, and the quantity of melted metal in the furnace and therefore its surface, is so small, that there would be very little time or opportunity for the heat to get lost. This furnace is based on the principle of the electric fuse which, as described above, is the most efficient form of electric furnace.

This imaginary extreme case points out the directions in which practical furnaces should tend to be developed, namely, rapidity of melting and smallness of charge.

In order to get some idea of the possible economy gained by applying the above principles, a series of furnaces for melting brass have been calculated and the results are given in the accompanying tables and curves. Actual figures have here been assumed for the melting energy and for the rate of losses, the total being equal to their sum. But as these basic data are not yet known: to the desired degree of precision these actual figures are only roughly approximate and no great weight should be placed on them; it is to the *relative* and not to the *absolute* results that attention is here called; on the other hand, these relative results would probably not be greatly different for more accurate basic data.

The basic data which have been assumed here are as follows: When there are no losses of heat it is assumed to take about 8.25 kwh. to melt 100 lb. of brass, including about 10 per cent. more energy to superheat it. This figure is not yet known definitely; it may be and probably is somewhat less; it is, moreover, different for different brasses; if too high it is on the safe side, hence is conservative. The weight of brass is taken to be about 540 lb. per cu. ft. It is thought that the loss through the walls may for brass temperatures be taken as about 1 kwh. per sq. ft. of surface of the charge;² this is also only approximate, but is probably not far wrong; it would probably require careful designing to bring the loss down to this figure. The electrode loss is assumed to be 20 per cent. of the total; this is believed to be liberal. The hearth is assumed to be

TABLE I.

SAME CHARGES—DIFFERENT RATES OF MELTING

Note.—Brass. Volume of charge 3.70 cu. ft. Diameter of hemispherical hearth 2.42 ft. Loss from charge 1 kw. per sq. ft. Electrode loss 20%. Theoretical consumption for melting and 10% superheating of 100 lbs. brass, 8.25 kwh.

Charge in Lbs.	Time of Melting in Hours	Rate of Melting in Pounds per Hour	Kilowatt-Hours for Melting	Kilowatts for Melting	Loss Through Walls in Kilowatts	Loss in Electrode in Kilowatts	Total Power in Kilowatts	Efficiency in Percentage	Kilowatt-hours per 100 Pounds
2000	4	500	165	41.3	13.7	11	69	60	13.8
2000	3	667	165	55.0	13.7	17	86	64	12.9
2000	2	1000	165	82.5	13.7	24	120	69	12.0
2000	1	2000	165	165	13.7	45	224	74	11.2
2000	0.5	4000	165	330	13.7	86	430	77	10.7
2000	0.25	8000	165	660	13.7	168	842	79	10.5
2000	0*	∞	165	∞	0	0	∞	100	8.25

*Imaginary theoretically perfect furnace in which there is instantaneous melting, like in an electrical protecting fuse

hemispherical in order to reduce its surface, and therefore the wall loss, to the least possible. In most furnaces these losses would probably be greater, hence the relative differences pointed out below would in most cases be still greater.

In Table I and Plate I, the data are given for a series of furnaces for melting brass each of which has the same charge, namely, one short ton of 2000 lb., hence all have the same size of hearth, but in each of them the charge is melted at a different rate; the slowest rate, 500 lb. per hour, would be considered slow in a fuel furnace of that size, while the most rapid rate, 8000 lb. per hour, would probably be quite impossible in a one ton fuel furnace. The last one in the table is an imaginary theoretically perfect furnace, given merely for the purpose of showing the absolutely extreme case.

²Possible Reduction of the Power Consumption in Electric Steel Refining Furnaces. Met. & Chem. Engineering, November, 1911, p. 590.

The total required power in kilowatts is made up of that required for melting, plus that lost through the walls (a constant in this case), plus that lost through the electrodes, these being the only two unavoidable losses. These component parts are shown by dotted lines in the plate, the total sum of all three being shown by a thick line.

It will be seen that as the speed of melting is increased the power in kilowatts, of course, becomes greater and quite rapidly so at the higher speeds, but the losses become less in proportion, hence the economy becomes considerably better for the higher speeds, as is seen by the efficiencies and by the kilowatt-hours required per 100 lb.; the latter is the crucial figure of interest to the user as it represents his power bill. It will be noticed from the curves that in this case the latter varies by a straight

PLATE I.—RESULTS FOR A SERIES OF BRASS FURNACES WITH THE SAME CHARGE, BUT OPERATED AT DIFFERENT RATES OF MELTING.

The relation. It will also be seen that the reason why the efficiency is so poor for the slowest speed is because the losses approach in amount to the power required for melting.

Table I and Plate I therefore show that, having a furnace of a given capacity of hearth, it pays well to force it as much as other conditions warrant. When the user generates his own power, greater kilowatts (greater speed of melting) means a greater cost of generating plant, which therefore tends to offset the advantages, hence the usual "happy medium" must be determined.

Comparing a slow rate of 500 lb. per hour with one of 4000 lb. it will be seen that although the latter is eight times as fast, the power is not increased in that proportion, 60 kw. compared with 430, but is only about 6.4 times as great. The efficiencies are 60 and 77 per cent., hence considerably more favorable for the higher rate. The power bills will be as 13.8 to 1.07 for the same quantity of metal; hence almost 30 per cent.

greater per pound for the slower rate. Hence the melting capacity of the plant may be increased eight fold with only about 6¼ times as much power, and the cost of power per pound of metal will be much less. Large foundries could, therefore, be operated cheaper than small ones, and the latter might to advantage do their casting in the shortest practicable time. Another illustration is given in Figs. 3 and 4 in the concluding summary.

Having now shown from Table I and Plate I, that with a given furnace of any stated capacity of hearth, it pays well to force it as much as conditions permit, the next feature to be discussed is the question of the amount of the charge, hence the size of the furnace, as the "ideal" furnace indicates that the smaller it is the better. This may sometimes be decided by other considerations than economy of power, as for instance by the weight of a desired large ingot or casting for which the charge is intended, and in such a case the only rule is to make the charge as small as one of these ingots or castings and not large enough for several, provided this is not impracticable. But assuming that one is otherwise free to choose the size of the charge an illustration of the relative results is given in Table II and Plate II.

In this second set it is assumed that the rate of melting has been fixed, and it is desired to know whether this can be done best with many smaller charges or with a few large ones. Here again the data has been estimated for a series of different furnaces, besides the imaginary perfect one. It is here assumed that the required rate is 500 lb. per hour. The data then shows the losses, power, efficiency, etc., of furnaces of different sizes, any of which will melt at this same rate of 500 lb. per hour. The same basic data is used as before, and the hearth is again assumed to be hemispherical. In the curves the kilowatts for melting, for supplying the losses through the walls, and in the electrodes, are shown by dotted lines, and their sum, the total power, is shown by a heavy line.

As the melting is now assumed to be done at the same rate in all, in pounds per hour, the power used (the kilowatts, not the kilowatt hours) for melting is the same for all, and its curve is therefore a horizontal line. The loss through the walls (the total, not that per pound of metal) is now the factor which increases rapidly as the furnace gets larger; this is due to the fact that the metal is subjected to this loss for a greater length of time.

It will be seen from the curves how greatly the efficiency improves as the furnaces are made smaller, and how fast the

TABLE II.
DIFFERENT CHARGES.—SAME RATE OF MELTING

NOTE.—BRASS, Rate 500 lbs. per hour. Hemispherical hearth. Loss from charge 1 kw. per sq. ft. Electrode loss 20%. Theoretical consumption for melting and 10% superheating of 100 lbs. brass, 8.25 kwh.

Charge in Pounds	Time of Melting in Hours	Volume in Cubic Feet	Diameter of Hearth in Feet	Kilowatts for Melting	Loss Thru Walls in Kilowatts	Loss in Electrodes in Kilowatts	Total Power in Kilowatts	Efficiency in Per cent	Kilowatt-hours per 100 lb.
2000	4	3.70	2.42	41.3	13.7	13.8	68.8	60	13.8

250	0.5	.463	1.21	41.3	3.5	11.2	55.9	74	11.2
125	0.25	.231	.96	41.3	2.2	10.9	54.3	76	10.9
		0	0	41.3	0	0	41.3	100	8.25

* Imaginary theoretically perfect furnace of infinitely small size, in which 2,000 lbs. are melted in 4 hours with continuous feeding and instantaneous melting.

kilowatt-hours per 100 lb. diminish as the furnaces are reduced in size; this is important to the user because that factor represents the power bill. (The curve for the latter happens to coincide with that for the kilowatts due to the scales here used; in all cases, however, the two quantities will be proportional under the assumptions here made.)

The conclusion to be drawn from Table II and Plate II is that for the same rate of melting, the smaller the furnace the more

economical it will be in power consumption; besides this the first cost will also be less. Hence the rule is to make the furnace as small as the desired charge will permit. If a certain ingot is desired make the charge equal to that one ingot and not to two or more. If the metal is to be cast into molds, make it equal to that for one mold; but as this may not always be practicable, then make it equivalent to as few molds as are.

As a concrete example taken from Table II, a 2000 lb. furnace may here be compared with a much smaller one for 125 lb., hence one-sixteenth. The large one will require about 69 kw. for 4 hours, the smaller one will require only about 54 kw. for the same 4 hours, and will deliver in that time sixteen charges of 125 lb. each, one every quarter of an hour, the rate of melting being the same in both. Hence there will be a saving of

PLATE 2—RESULTS FOR A SERIES OF BRASS FURNACES OPERATED WITH THE SAME RATE, BUT WITH DIFFERENT CHARGES

about 15 kw. in favor of the smaller one. The energy consumption, and therefore the power bill, will be at the rate of 13.8 kwh. per 100 lb. for the large one, as compared with 10.9 for the small one, or about 27 per cent. better, in favor of the smaller one. Another comparison is given in Figs. 2 and 3 in the concluding summary.

As stated above, there will often be other conditions which will determine the limit to which one can go in increasing the rate of melting and decreasing the charge, and therefore the size of the furnace. The above discussion merely shows the directions in which one should tend to go in designing a furnace, other conditions permitting.

There are also some other minor factors which, for the sake of simplicity in an analysis which is already somewhat involved, are not considered here and which in some cases may affect the conclusion more or less; their importance should be examined in each case. It is true, for instance, that in a large slow-speed furnace the temperature is not at the maximum at the start,

hence the wall losses will at first be less. The extra labor of filling and emptying a small furnace frequently instead of a large one less frequently, should also be considered. On the other hand the very appreciable reduction in first cost of a smaller furnace for the same daily output, has not been considered here; nor the advantages of a reserve unit which may become practicable when the furnaces are small and cheap. Also the saving of labor, superheat, crucibles, their preheating, etc., when the furnace becomes small enough to be transported to the molds. The engineer must, of course, consider these and many other factors in his final decision.

The academician may find entertainment in expressing the above deductions in algebraic form. The writer believes that a series of concrete examples like those in these tables and curves, gives a clearer insight to the relations than abstract figures and letters do. Moreover, algebraic analyses are often burdened with complicated factors which in practice turn out to be negligible quantities.

Summary.—The general conclusions of this analytical investigation may be briefly summarized as follows:

The total consumption of energy per pound of metal, and

therefore the power bill, will decrease quite appreciably: (a) the more rapidly the melting is done, and (b) the smaller the charge, and therefore the furnace; both might be combined by saying: the less the time that each pound of metal is held in the furnace. This is based on the energy required for melting and the losses in the walls and electrodes. Such reductions in the size of the furnace also diminish its first cost and may in some cases make it portable so that it may be taken to the molds; the ideal melting furnace for small castings is one which melts as fast as it can be moved from mold to mold, and poured; for small brass castings such a design is not impracticable; the same may be true for small steel castings also.

No great importance should be attached to the approximate actual figures for brass melting furnaces given in the tables, although they are probably not far wrong; attention is here intended to be called chiefly to the relative values.

Pictorially these deductions concerning the relative values may be represented by the following diagrams Figs. 1-4, which are based in part on the tables and are drawn to scale. Another feature which was brought out in a previous paper is here included because it at first sight appears to be contradictory, but in fact is not.

Figs. 1 and 2 show that it is much more economical in power and in plant cost to use one large furnace instead of eight smaller ones of the same combined capacity of metal when all the smaller ones are being operated at the same time. This was described in a previous paper. Fig. 1 represents usual foundry practice in that a large number of small furnaces is used, all operating together. The rate of melting here assumed would be considered a moderately slow rate for fuel furnaces.

Figs. 2 and 3 (illustrating Table II and Plate II) show that it is much more economical in power and in plant cost to melt smaller charges at a time and to melt them in succession in the same furnace, though at the same rate of melting; the furnace will then also be considerably smaller. The smaller furnace of Fig. 3, though melting no faster than the large one, namely, 500 lb. per hour, will have the same daily output and will be more economical in power consumption.

In electrical parlance, Figs. 1 and 3 show that it is far more economical both in power and plant cost to melt the charges "in series" than "in multiple."

Figs. 3 and 4 (illustrating Table I and Plate I) show that it is much more economical in power to melt a given charge quickly, four times as rapidly in this particular case. The same is shown to a more striking degree by comparing the furnace of Fig. 3 with one of the eight furnaces of Fig. 1. The rate of melting assumed in Fig. 4 is about fifteen to twenty times as fast as the usual rate with fuel furnaces of that small size, and is approximately the rate used in a large 20-ton reverberatory furnace.

Comparing the two extreme cases with each other, namely, Fig. 1 and Fig. 4, it will be seen that Fig. 1 represents in general the usual foundry practice of to-day in so far as a large number of small furnaces are operated together; while Fig. 4 represents what would seem to be the best practice with electrical furnaces, namely, a single small furnace melting rapidly a large number of small charges in succession. A comparison of the data of Figs. 1 and 4 will give an idea of the very marked increase in economy obtained by the small, quick-acting furnace.

The furnaces of Figs. 1, 2 and 3 all have the same daily output, while that of Fig. 4 has four times as great an output per day, although it is no larger than that of Fig. 3.

Philadelphia, Pa.

Reform of Procedure in Patent Suits by the New Rules

By Dyer Smith

It is perhaps not fully known among manufacturers and inventors that a quite new method of procedure in the trial of suits for the infringement of patents went into effect Feb. 1. This change results from the new rules of practice for the Courts of Equity of the United States, promulgated by the United States Supreme Court.

New Rules of Practice for the Courts of Equity, Promulgated by the Supreme Court

The new practice will undoubtedly, in most cases, cause greater expedition and lessened expense to litigants, because of a general simplification of procedure, removal of causes for delay, and shortening up of times within which action may be taken. Especially, it is believed, will these beneficial results spring from the requirements of the rules that testimony shall be taken, in all usual cases, orally in open court, before the judge.

Under this new practice, the testimony is taken in one continuous session, in court, followed by the arguments of the lawyers, and the parties and the judge give their attention entirely to the matter at hand until its conclusion.

The rules now in force take the place of those originally promulgated in 1822 and 1842 and not changed greatly since the latter date. The present revision is the work of a committee of Supreme Court justices, aided by committees of lawyers residing in the nine circuits into which the United States

is divided. The changes which have gone into effect as the results of their labors are considerable, and, while some of the innovations will have to be "worked out," the new practice is clearly a greater boon to the owners of patents.

Under the old practice testimony was almost always taken out of court, in patent suits, and reduced to writing to be read by the judge after the hearing by him of the lawyers' arguments. It usually ran to a considerable length, and was generally more expensive and unsatisfactory, it is believed, than the testimony in open court of the new practice. The former methods were a continual cause of complaint to inventors and manufacturers, so that it was commonly said that a poor litigant had no chance in a patent suit against one well supplied with funds. The aim of the new rules is to remedy this condition as far as possible.

The first point to be noted in the new rules is that the technical forms of pleadings in equity, generally speaking, are abolished. Demurrers and pleas, always strongholds of delay, are done away with, the defenses formerly presented by these forms of pleading now being made in a simple way by motion to dismiss the bill or being incorporated in the answer. The answer of the defendant now merely sets out in short and simple terms the defense to each claim asserted by the bill brought by the plaintiff against him, avoiding general denials, but specifically admitting or denying or explaining the facts upon which the complaining party relies in his bill.

The answer must also, briefly and simply, state any counter-claims or set-off which the defendant may have, arising out of the same transaction as that upon which the bill of complainant was brought, or which might be the subject of an independent suit in equity against the opposing party, thus permitting various matters to be settled in one suit which might otherwise require the filing of cross-bills or bringing of separate suits by the defendant against the plaintiff. The bill of complaint, according to the provisions of the new rules, is to be framed in as simple and concise a manner as possible.

Not only are the pleadings simplified, but the times within which they can be filed are considerably shortened. The subpoena issued when the bill of complaint is filed is returnable in twenty days, to the office of the clerk of the court, and the defendant is required to file his answer or other defense in the clerk's office within twenty days after the subpoena has been served on him. Otherwise the bill may be taken *pro confesso*, unless the time be enlarged by a judge, for cause shown. When twenty days is not enough for the preparation of a defense, as in a suit on a patent in a technical art, involving the search for and study of many prior patents and publications, more time will, of course, be given, but the United States judges are all disposed to enforce the spirit of the new rules, and delay cannot be obtained against the opposition of the other side unless some good reason therefor is shown.

The pleadings will be concluded immediately upon the filing of the answer, and the controversy then deemed to be at issue, without the subsequent filing of a replication by the plaintiff, as formerly, unless the defendant sets up a counter claim or set-off in his answer, in which case ten days is allowed the plaintiff to answer this. The case is then ready immediately for the taking of testimony and trial.

As stated above, the testimony is now usually taken orally in open court. That is to say, a day for trial having been set and the parties having prepared their respective cases as fully as possible, in advance, the proceedings will be begun and usually carried through uninterruptedly to a conclusion before the judge.

The plaintiff's lawyer will first address the court, explain briefly his client's patent and outline the case of infringement he expects to prove. The defendant's counsel will then briefly outline the defense he expects to make. Complainant's witnesses will then be sworn, examined and cross-examined by the opposing counsel until the plaintiff's attorney deems he has won or lost a case. The defendant's witnesses will then be examined, and the defense made clear by the testimony, including, in most cases in which an unadjudicated patent is sued

upon, an attempt to prove the patent in suit invalid in view of certain prior patents or publications which the defense sets forth and explains. The plaintiff then immediately takes his rebuttal testimony, after which the opposing lawyers sum up and the case is left with the court.

This proceeding has taken only a few days, in place of the months and often many years consumed under the old practice in taking testimony in typewriting before a notary public or other so-called examiner, usually in the office of one of the lawyers. The judge has had the opportunity of seeing the witnesses while they give their testimony, of forming his opinions as to their frankness and apparent credibility, and of asking questions when a technical or other point is not clear to him.

He rules immediately upon any question of the admissibility of evidence which arises, and evidence which is clearly immaterial is not allowed to take up time in presentation and space in the record. When he feels that a point has been fully presented, and is clearly understood by him, he will indicate to the examining lawyer that nothing further is required along that line.

At the end of the trial the judge in most cases will have such a clear understanding of the matters at issue that he will be able to hand down his decision from the bench; or if he wishes to take the matter under advisement and hear further from the lawyers by written briefs as to any particular points of law which may have arisen, a shorter time additional than formerly will be required.

The saving of time in this respect will, of course, depend upon the judges themselves and the number of cases they have to hear. If a judge postpones the preparation of his opinion until after numerous other cases have been heard, the saving in this respect will not, of course, be so great. There is now, however, clearly the possibility of getting an opinion from the bench or shortly after the end of the trial, whereas formerly there could not be an opinion until after the judge had considered the records of testimony, etc., which was always done some time after the final hearing.

This form of procedure will doubtless reduce the cost of taking testimony very materially. The records of patent suits under the old practice were often "padded" with immaterial matter and almost always were longer than necessary. This was for the reason, first, that the examiner before whom the testimony was taken had not authority to pass upon the admissibility of evidence. Everything offered was taken down, together with the objections of the opposing counsel, if any.

The lack of power of the examiner was often taken advantage of, and the rules of evidence sadly mistreated by lawyers who wished to get certain testimony upon the record, regardless of its propriety in the case. This greatly increased the cost of the record of the testimony, exhibits, etc., which was usually printed before trial, and also the labor of the judge in reading through the same after trial.

Another reason for the longer records under the former practice was the difficulty of the lawyer in knowing when he had proved enough to make the matter comprehensible to the court, which would later derive its information by reading the record of the testimony. Another cause was the tendency of certain experts and other witnesses to spar and answer by lengthy indirection to embarrassing questions put. These exercises of mental gymnastics have sometimes consumed an excessive amount of time and will certainly not be attempted, or permitted if attempted, when the testimony is taken before a judge in court.

The causes above referred to have often resulted in patent cases in records of many printed volumes of testimony and in lengthy printed briefs submitted by counsel referring to or sometimes quoting at length from the most pertinent parts of the testimony. In such a case it is almost a certainty that the hard-worked judge will not fully read the entire record of the case, but will rely largely on the extracts brought to his attention by the opposing counsel.

Thus, under the old practice, we had the following elements in the trial of a patent case: volumes of testimony taken with

great toil and at considerable expense, with none of which the judge was familiar before the hearing; then the arguments of counsel before the judge, largely directed to giving him the fundamental information required to pass upon the questions involved; then a long period of waiting, in which the judge grappled with the printed records and briefs in whatever time he could find from his study of other records and the hearing of arguments in other cases. At the end of this period the decision was handed down. In one case in my experience the decision was not rendered for about fourteen months after the argument, so that the points made at the argument could hardly have stood out very clearly in the judicial mind at the time the opinion was written.

The new rules cannot fail to make a procedure immensely more rational and expeditious than the above. In one suit with which I am familiar, tried, by consent of the parties in open court in New York the latter part of January, the bill of complaint had been filed the previous October, just three months previously. The suit was on a mechanical device of some complexity, and the theory of operation of this device and those of the prior art set up by the defendant involved the consideration of various mechanical principles. The devices were explained fully to the court by working models, and the whole trial consumed only two days and a half. Decision was reserved in this case, but it is expected very shortly at this writing.

Depositions may be taken out of court under the new practice in exceptional cases only. They will only be permitted upon the application of the party desiring so to take the testimony in cases in which this mode is permitted by statute or when the moving party shows, by affidavit, a good and exceptional cause for departing from the general rule.

Certain sections of the Revised Statutes of the United States provided for the taking of testimony before an examiner, if desired, in the case of witnesses who live more than 100 miles away from the place of trial, and the Supreme Court rules cannot, of course, abrogate this statute. The rules provide, however, that if proper notice of the taking of such testimony has not been given the opposing party, the latter may be entitled to have the witness examined orally in open court if the court deems it proper under the circumstances.

If depositions are taken out of court, under a statute or order of the court, the names of all the witnesses must be given to the court in advance and the testimony must all be taken in a limited time, unless otherwise ordered by the court for good cause shown, sixty days for the plaintiff, thirty more for the defendant and twenty for rebuttal depositions.

The equity rules formerly in force also provided for limited time for the taking of testimony, but this was more honored in the breach than in the observance. As stated, the federal judges now are all determined to strictly enforce the provisions of the new rules with a view to expediting proceedings in all cases in which some good reason for delay is not made to appear.

Special provisions are made for the taking of the testimony of expert witnesses in patent and trade-mark cases. Such witnesses may, and in many cases will, be examined in open court according to the general rule. The court may, however, upon petition order that their direct testimony be set forth in affidavits and filed in a limited time; forty days for the plaintiff, twenty days more for the defendant, and fifteen days more for rebuttal affidavits. Should the opposing party wish to cross-examine any of these experts the court may order that such cross-examination and any re-examination take place before the court upon the trial, and unless the expert is produced for such examination his affidavit cannot be used.

Cases are now placed on the trial calendar as soon as the time has elapsed for taking and filing depositions, where these are permitted by the new rules. Thereafter no further testimony shall be taken by deposition except for some strong reason shown by affidavit. That is, even when some of the testimony is permitted to be taken out of court by deposition, as where witnesses live in a distant place, the case will go on the trial calendar after 110 days have elapsed since the case

was at issue. The federal courts all over the country are now calling these trial calendars, and patent suits which have been dragging for a long time are being disposed of or dismissed for want of prosecution.

The Rules of the District Court for the Southern District of New York

The District Court for the Southern District of New York, in which Manhattan Island is situated, have also promulgated new rules, which went into effect on Feb. 1, 1913. It is then provided that in patent cases each side shall be allowed only one expert witness unless leave to employ more be granted on cause shown.

This court also rules that expert witnesses, where their testimony is taken by affidavit as provided for in the Supreme Court rule referred to above, shall confine their testimony strictly to an explanation of the operation of relevant arts, processes, machines, manufacturers, or compositions of matter, and of the meaning of terms of art or science and of diagrams or formulas. They shall not give their opinion as to the meaning of any patent claim or specification, and if matter is hidden by this rule, or irrelevant or immaterial matter is contained in an affidavit, it shall not be answered by the opposite party nor be the basis of any cross-examination and the court may at any time strike such matter from the deposition.

This provision will doubtless result in much shorter expert depositions than most of these formerly taken. The rule is so novel that its actual working out in practice will have to be awaited before its relative merits and disadvantages can be accurately determined.

Another interesting paragraph in the New York rules is one which provides for the engagement of an expert to assist and sit with the judge at the hearing of the evidence in the trial of a patent case which in the opinion of the court involves intricate technical or scientific questions of fact. In such a case when all parties consent the court will appoint some disinterested person skilled in the art to act as an assessor, as it is termed by the rules, the reasonable fees for whose services are to be fixed by the court and charged as part of the taxable disbursements. The assessor will sit with the judge, assist the latter in his deliberations when requested and render the judge a written opinion when the court desires it, which shall be a portion of the record, on appeal.

It is believed that this rule should prove beneficial, provided a disinterested expert can be found acceptable to both sides in a given case. This may often be difficult, and many parties will prefer to await the trying out of the scheme before consenting to try it in their own cases.

The rule is designed, however, to meet the objection often urged by critics of our patent system that a judge, learned in the law, but not especially trained in technical sciences, should not be left unaided to decide important patent suits, the determination of which may depend upon a nice appreciation of intricate chemical or physical phenomena or a highly technical art.

It is a testimonial to the value of the legal training that judges lacking in special scientific education are as able as they are to lay hold of the important point of such a controversy and rightly determine the merits of the case.

Such an assessor, if broad minded and unbiased, will doubtless be of great assistance to the court in cases in which the opposing experts hold widely differing views. This official should not, of course, usurp the functions either of the court or of the witnesses, and will doubtless merely advise the court, upon request, in the interpretation to be given the testimony and the correlation of technical facts. The working of this innovation will be watched with great interest.

A considerable saving in expense to patent litigants under the new practice should appear in the matter of making up the record. The testimony taken in open court or before the trial need not be printed, as it formerly was in most cases, but will usually be taken down in shorthand by an appointed stenographer, and, if required, transcribed. When a case is appealed to the higher court the evidence to be included in the record

for the upper court will not be set forth in full and printed, as formerly, but will be stated in simple and condensed form, usually in the narrative manner; and those parts only which are essential to the decision of the questions presented by the appeal will be presented. The statement and condensation of the evidence for appeal will be made by the parties under the direction of the court, and all formal and immaterial parts of documents are to be excluded.

The system above briefly outlined is believed to be fundamentally sound and a conclusive answer to many of the criticisms of the former practice. Its advantages will appear in proportion as it is enforced by the courts and lived up to by the parties themselves. Unnecessary delays in patent litigation will occur chiefly when they are agreed to by both sides. Even in such cases suits will not be allowed to slumber in the peace of former years. The District Court sitting in New York City, for example, ordered some time ago that all suits in equity filed since 1902 be brought forth and placed on a special calendar, which was heard the first week in March. This resulted in hundreds of suits which had not been actually prosecuted for several years being dismissed. The same sort of a cleaning-up process is being carried out in the other District Courts of the country.

As to the possible disadvantages of the new system, it may be remarked that cases will have to be prepared in advance with the greatest thoroughness, and the defense anticipated by the plaintiff sufficiently to have the rebuttal witnesses primed and in attendance, since there will usually be no period of delay between the taking of defendant's proofs and the presentation of the rebuttal.

The hardship, however, if any, will be more than counterbalanced by the advantages, among which may usually be included the lack of opportunity to prepare defenses too fine-drawn to the facts and opinions educed by the opposing party. The cause of truth will probably be advanced when well-trained witnesses are given no considerable time to revise their views and testimony.

The fact that testimony in open court is not immediately typewritten, as in the usual former practice, but is buried for the day at least in the notebook of the court stenographer will also be embarrassing to some forgetful or uncertain witnesses, but will inure to the advantage of frankness and consistency.

The amount of gain in time required to secure a decision under the new practice will depend somewhat upon the calls upon the time of the judges. The actual hearing of patent cases, will, of course, consume more time now than formerly when in the usual equity case the judge only heard the arguments of counsel upon the evidence previously taken. On the other hand, the judge will be saved a good deal of time previously needed in reading the heavy printed records of testimony. In order to get the best results from the new system it may be that a number of additional federal judges will need to be appointed.

It seems clear that the Supreme Court has accomplished a constructive and well-considered reform by its new rules, for which the inventors and manufacturers of the country should be thankful. It is the more welcome since Congress has so merged and confused the inventor's demand for patent reforms with the supposed popular cry for greater regulation of all monopolies as to result in bills being introduced which would leave the inventor with less rights and remedies than before. There is probably little cause to fear that these bills will pass without material changes, because of the widespread protest against them on the part of patentees and technical interests, but even if they should pass a positive gain has undoubtedly resulted from the action of the Supreme Court.

New York City.

The gold output of the Rand to date amounts to a grand total of about \$1,685,000,000. Of this sum about \$44,375,000 has been paid in dividends. The production in 1912 broke all records, amounting to about \$180,000,000, and equalled about 40 per cent of the gold production of the world.

Iron Pipe Used for Electric Conduit

By Oliver W. Storey

The manufacture of rigid metallic conduit has become an industry of importance to the chemical engineer during the past decade. The competition among the manufacturers of this class of material has become very keen and has helped to develop a variety of methods of treating pipe to make it conform to the requirements of the National Board of Fire Underwriters. As the competition increased, the quality of the finished product increased and now the conduit is of a very high grade.

An electric conduit system may be defined as "a raceway in a building to provide for the ready introduction and removal of electric wires and to provide efficient mechanical protection to them."

This definition requires the following necessary features for such a conduit. It should occupy the least possible space; it should be rugged and mechanically strong, yet be easy to work and install; it should resist corrosive action and it should efficiently protect and preserve the insulation of wires contained in it; and it must be moderate in cost.

Materials possessing all of the qualities mentioned are available but their cost is prohibitive. Ordinary iron or steel pipe is cheap and possesses all of the necessary qualities except resistance to corrosive action, but by treating it to certain processes it becomes available for conduit purposes. It is the purpose of this article to describe these various methods of treatment and their comparative durability.

In the past many substances were used for the manufacture of conduit such as fibre, paper, rubber and moulded pulp. Metal pipe was also lined with paper, wood or compositions but these methods have been practically abandoned for the present practice.

At the present time butt-welded mild steel pipe 10 ft. long is used for conduit. This makes a cheap and excellent base since it is very rugged and can be easily worked.

The present manufacture of unlined conduit may be divided into two general classes, enameled and galvanized. The enameling affords protection to the pipe by a corrosion resisting film of enamel while the galvanizing affords protection by galvanic action.

It is only within the past few years that the sale of galvanized or so-called "white pipe" in contrast to the black enameled or "black pipe" has reached large proportions with a consequent decrease of production of the latter. This condition is caused primarily by the reduction of price of galvanized conduit with increasing competition and also by the general conservation tendency in the iron and steel trade to secure a maximum of protection even with greatly increased cost.

In this article the cleaning of the pipe previous to galvanizing or enameling will not be described. The subject of pickling of conduit pipe is an extensive one and has been discussed in another article.¹ It is assumed that all pipe is clean and in a condition to turn out a good grade of conduit.

Manufacture of Black Enameled or "Black Pipe"

The manufacture of "black pipe" appears as a simple proposition, but the large number of difficulties that appear in carrying out the process of enameling requires a great deal of technical skill to insure success.

The selection or compounding of a suitable enamel is of primary importance. Such an enamel when baked must conform to the specifications of the National Board of Fire Underwriters which are as follows: Section 58, Rule 1: "The pipe from which the conduit is made must be thoroughly cleaned to remove all scale and must then be protected against effects of oxidation, by baked enamel, zinc, or other approved coating which will not soften at ordinary temperatures, and of sufficient weight and toughness to successively withstand rough usage likely to be received during shipment and installation; and of sufficient elasticity to prevent flaking when 1/2-in. conduit is bent in a curve the inner edge of which has a radius of

¹Met. & Chem. Eng., Vol. 11, No. 1, p. 45.

3½ in. All conduit must have an interior coating of a character and appearance which will readily distinguish it from ordinary commercial pipe commonly used for other than electrical purposes."

Other large users of conduit issue specifications that are usually more rigid. Typical of these are the "Specifications for Conduit and Conduit Fittings" issued by the U. S. Navy Department of May 20, 1912. The sections relating to enameled conduit follow:

a. The enamel shall be of an approved type and be not less than 0.005 in. in thickness.

b. Not to be affected by moisture or at a temperature of 100 deg. C.

c. To be of sufficient elasticity to prevent flaking and to adhere with smooth surface when conduit is bent at normal temperatures in a curve, the inner surface of which has a radius of seven times the normal I. P. S. for ½ in. and to times the normal I. P. S. for all other sizes.

d. Not to be affected by the following after an immersion of 24 hours:

1. A 30 per cent solution of sulphuric acid.

2. A 30 per cent solution of nitric acid.

3. A 30 per cent solution of hydrochloric acid.

The specifications of the Board of Underwriters will allow much cheaper enamels to be used than those of the Navy Department. The latter's requirements are very exacting and only the best of enamels may be used.

The baking enamels used contain linseed oil as a base. The other constituents are tars, asphaltums, pitches, and gums, giving it its black color. The usual thinner is benzine. The enamels are made in many grades depending upon the amount of linseed used. By using a small percentage of linseed oil and a large proportion of asphaltums dissolved in benzine a very cheap enamel baking at a low temperature may be made. By using a high percentage of linseed oil with dissolved gums and asphaltum added an excellent one baking at high temperatures may be made. The addition of small percentages of other materials is practiced to improve certain qualities.

A method of testing for a good enamel is as follows:

Remove a strip of enamel from the pipe with a sharp knife. This strip should approach rubber in its elasticity and yet should be hard enough while on the pipe not to be easily scratched by the finger nail. Even after ageing for several years in a warm dry atmosphere this test should still apply.

The general methods used in conduit pipe enameling are alike and differ merely in details. The pipe is hung on racks and dipped into a tank of enamel, and after withdrawing and dripping is run into an oven and baked.

The clean, dry pipe coming from the pickle room are ready for enameling. The couplings on one end found necessary to secure complete separation of the pipes in the pickling vat are again found necessary to hang them upon the enameling racks.

The racks are usually made of cast iron with a double row of notches into which the pipe will slip easily but upon which the shoulders of the coupling will rest. With small sizes of pipe the notches may be deep enough to support two lengths. The racks are supported by a monorail system. The capacity of each is from 50 to 200 ½-in. pipe and requires a different rack for each size of pipe. Since a large percentage of conduit is ½ in. the number needed for the other sizes is small especially for those above 1 in.

After the pipes have been hung upon the racks they are dipped into the enamel which is usually contained in a riveted iron tank about 11 ft. deep, 2 ft. wide and long enough to accommodate the dipping rack. The tanks often contain 1000 gallons of enamel. With an enamel worth 65 cents per gallon the value of the contents is a considerable sum and precautions must be taken to prevent its becoming ignited, to prevent any deleterious foreign matter entering it or to prevent adding a poorer quality of enamel which necessitates testing of all new lots of enamel.

The danger of fire is increased by heating the enamel by steam coils in the bottom of the tank. The heating is neces-

sary to maintain a constant temperature and to thin the enamel. This method is safer, cheaper and gives better results than thinning with benzine. If a volatile solvent is added the enamel continually changes in consistency with corresponding variation in the finished product. Warm enamel also coats the pipe more evenly by eliminating any air bubbles clinging to the pipe surface.

The rack of pipe is lowered into the enamel and allowed to remain until it has reached the same temperature. It is then hoisted out of the tank and the pipe allowed to drip for about a minute after which they are run over dripping pans and allowed to remain until ready for baking. The excess enamel on the dripping pans flows back into the tank.

With the various grades of enamel this preliminary air exposure accomplishes different purposes. With a high grade, high temperature baking enamel this exposure to the air does not cause any hardening of the enamel but merely allows some of the excess enamel to drain. With a medium grade, benzine-thinned enamel the benzine evaporates, leaving a jelly-like coating that hardens in the furnace with medium temperatures. With a cheap enamel containing a larger percentage of benzine, the latter evaporates leaving an enamel that is but slightly tacky and which becomes hard with a slight baking.

After the preliminary air treatment the pipes are run into the baking oven. These vary in their construction and in capacity which is usually rated in terms of ½-in. pipe. An oven having a capacity of 25,000 feet of ½-in. pipe would hold about 4000 ft. of 4-in. pipe.

The design of the baking oven is dependent upon the enamel used. In general they are made of firebrick with ample ventilation for all fumes and gases evolved.

If a low temperature baking enamel is used steam coils may be placed in the bottom of the oven and adequate heat furnished by these to finish the drying of the enamel.

Where higher temperatures up to 700 deg. Fahr. are desired two general methods are in use, the direct and indirect.

The direct method is used where natural gas is available or other gas can be obtained at low cost. The gas is burned directly in the baking oven in a kind of hearth or brick that are heated to a white heat. The object is secure as complete combustion of the gas with as little excess of air as possible. The hot gases of combustion circulate among the pipe and bake the enamel. With small excess of air there is little danger of igniting the fumes evolved. With incomplete combustion soot would be deposited upon the tacky enamel and spoil it.

With the indirect method of heating the hot gases of combustion are led through radiators which heat the air to be used in baking the enamel.

The efficiency of the direct method is very high when compared to the indirect. With the latter there is no danger of spoiling the enamel with the products of combustion and there is no danger of an explosion should the oven door be accidentally opened during the "heat."

When a medium enamel which hardens slowly in the air is used the oven is run at a temperature of 300 deg. to 400 deg. Fahr. When the oven is first warmed a small amount of enamel may drip from the bottom of the pipe due to the thinning of the jelly-like film left after the evaporation of the solvents.

With one that must be baked at a temperature of 600 deg. Fahr. the operation is not as simple. When the oven warms the enamel thins and the excess will drip to the bottom of the furnace. This dripping will continue for some time, usually until the solvents have evaporated and the linseed oil has begun to harden. The excess is drained into a well from which it is periodically returned to the tanks, apparently having suffered no deterioration.

The securing of a uniform film of enamel over the surface of the pipe is a difficult problem. After baking a rack of ½-in. pipe, that have received one coat of enamel, the following imperfections will be noted:

1. The upper end of the pipe, both interior and exterior, has received a thinner and harder coating than the lower end

2. The threads at the lower end are filled with enamel.
3. The surface of the exterior of the pipe that is very close to another pipe has a coating thin enough to be transparent, while the balance of the pipe has a heavier coating.
4. The interior surface of a piece of $\frac{1}{2}$ -in. pipe has received a thin coat while the same surface on a piece of 4-in. pipe is as heavily coated as the exterior.

These are the chief difficulties encountered in enameling conduit.

The coating at the upper end of the pipe is usually half as heavy as that at the lower end. This is caused by the upper part of the enameling oven becoming hotter first and the draining of the surplus enamel to the bottom of the pipe. The enamel flows slowly to the lower end, and, before it can all drip, it has begun to harden since the rate of heating is usually high. With slower heating this difficulty could be lessened. At the upper end of the pipe it is also harder than at the lower owing to the thinner film and higher temperature.

These imperfections may be remedied in the second application by upending the conduit on the racks. This is not generally done owing to the extra operation of changing couplings which would require that the racks be unloaded and reloaded. Some manufacturers depend upon the second coat being more uniform than the first and covering any pronounced difference in the upper and lower end.

The unevenness of coating due to the proximity of other pipe can obviously only be remedied by cutting down the capacity of the oven. Since the second coat of enamel covers this defect it is usually disregarded. If but one coat of enamel were used this defect would have to be remedied.

The difference of thickness between the interior and exterior coat is primarily caused by the lack of circulation in the interior of the pipe and consequent slow evaporation of the solvents and slow oxidation of the oils, allowing more enamel to drain. The enamel film is also very thin at the top when compared to the bottom. As the size of the pipe increases these difficulties decrease.

The two coats of enamel are necessary to give a flexible coat of suitable thickness as required by the specifications and to overcome some of the defects mentioned. A coat of the requisite thickness could not be applied in one baking for the same reason that a thick coat of paint is never used.

The second coat is applied in the same manner as the first and results in a bright smooth surface. This coat is usually baked at a slightly higher temperature than the first giving a harder surface, yet flexible owing to the softer foundation. A third coat is sometimes required but such an additional film is of doubtful value as an added protection.

The conduit is now ready for the market after an inspection of the bore to discover obstructions. This inspection is carried out by flashing a light through it.

The enamel interior provides a smooth raceway for wires. Its generally excellent appearance, its cleanliness, smooth interior and its cheapness makes the black pipe very popular among the installers.

The racks used for dipping the pipe soon become covered with enamel and unfit for use. This can be easily removed by burning in a scrap fire.

Elbows are finished by running wires through the bores and dipping them as with pipe.

The enameling plant should be so planned that the process may be carried on without interruption during the different operations. The layout should allow enough space to provide for the hanging of an oven-full of green pipe and enough dripping space to take care of an oven-full of dipped pipe. The mechanism should be so arranged as to allow a batch of baked pipe to be removed from the oven while a second batch is run into it. During the baking of this, the first can be given its second dip and allowed to drain.

Since the quality of the enamel is dependent in a large measure upon the temperature control of the ovens, recording gauges should be used to keep an accurate record of the temperature at various parts.

Methods of Manufacture of Galvanized or "White Pipe"

While the general practice in the manufacture of "black pipe" is essentially the same at all plants, the practice in the "white" or galvanized pipe industry varies widely. This difference is due primarily to the three galvanizing methods used, these being hot galvanized, electro-galvanized and sherardized. Approved conduit of all these three types are on the market, the electro-galvanizing predominating since the one sherardized conduit is patented, and there has been but one hot galvanized conduit approved by the underwriters.

The specifications of the Board of Underwriters have been quoted and are easily complied with. In direct contrast are the rigid specifications of the Navy Department which exclude hot galvanizing.

"2. h. All steel conduits shall have the exterior surface galvanized and the interior surface either enameled or galvanized and enameled. All galvanizing shall be done either by electro-plating process or dry galvanizing process, and shall show no signs of rust when conduit is immersed in warm salt water (90 deg. C.) for 48 hours. The outer surface of conduit shall be free from paraffin or other material which would tend to prevent the adhesion of paint. Before any tests are made, conduit shall be washed thoroughly in carbon tetrachloride.

"3. d. 4. When conduit is both enameled and galvanized on inside tests under 3. (d) 1, 2, and 3 (acid tests) will not be applied."

The chief trouble that has been encountered in the manufacture of hot galvanized conduit has been the wiping of the interior of the conduit to secure a thin, flexible, and adherent coating. The present hot galvanized conduit on the market has a smooth wiped interior and exterior surface while the threads are clean, yet well coated and need no recutting. The coating is somewhat heavier than is found on electro-galvanized or sherardized pipe yet it is flexible and adheres well to the iron base.

This coating contains aluminium in varying amounts, often being as high as 10 per cent. The addition of this metal improves the hot galvanizing bath without materially increasing the cost owing to its low specific gravity. The aluminium gives the finished conduit a pleasing white appearance.

The presence of about 4 per cent of aluminium reduces the melting point of zinc from 788 deg. Fahr. to 716 deg. Fahr., and allows the bath to be run at lower temperature and decreasing the amount of zinc-iron alloy formed. Since 4 per cent is the eutectic percentage any other low percentage of aluminium will make the solidification occur over a shorter or longer range of temperature depending upon the composition and will, therefore, make it easier to wipe.

The interior of this hot galvanized conduit is not enameled but a peculiar blue black wash is used. It is a thin coating and is merely used as a distinctive finish and helps the fishing qualities slightly.

The one sherardized conduit is made by the sherardizing process and has a coating of zinc-iron alloy on the interior, exterior, and threads. While it is not as heavy as that obtained by the hot galvanizing process it is much heavier than that obtained with the electro-galvanizing. It adheres firmly to the iron base, does not flake and is hard, making it capable of withstanding rough usage.

Analyses of the zinc-iron alloy made at different times will show varying amounts of iron present. The iron varies with the metallic zinc in the zinc dust, thickness of coat, sherardizing temperature and length of time in the furnace. The amount of iron in the alloy has been subject to a great deal of discussion since the different investigators have found widely varying percentages. Patrick and Walker¹ found 11.70 per cent, Leighou and Calderwood² 18.15 per cent, while Cushman³ found about 30 per cent. In none of these cases was

¹ *Trans. I. & E. Ch.*, Vol. 8, No. 4, p. 219.

² *Reports of Tests on Sherardized and Electro-galvanized Conduits*, Carnegie Inst. of Tech.

³ *Bureau of Zinc Coated Conduit Pipes*, Inst. of Industrial Research, Washington.

it known under what conditions the alloy was formed. From a large number of analyses made by the author it was found that the above variables determined the iron content of the alloy formed. By controlling these factors any zinc-iron alloy containing from 8 to 30 per cent of iron may be obtained.

Sherardized conduit receives an exterior and interior coat of clear enamel. Previous to this practice a coat of clear enamel was put upon the interior only and the exterior was paraffined. The clear enamel was used to aid fishing while the paraffin was used to lay the objectionable loose zinc dust that remained on the pipe.

Electro-galvanized conduit is made by varying methods. Only the exterior is plated since the plating of the interior has not been put on a commercial basis. Usually the threads have little or no coating on them, the interior of the couplings are rusty and elbows are poorly coated. With one exception the zinc coating is thin.

One brand of conduit is made by flashing the cleaned iron pipe in a copper bath and plating over this copper with zinc.

Another manufacturer obtains a smooth velvety adherent coating by wire brushing the pipe before coating with zinc. A second brushes the conduit after plating and obtains a bright finish which is pleasing to the eye and does not discolor easily.

All "white pipe" is enameled in the interior to help the fishing and with the cold galvanizing to provide against oxidation of the iron. In the Navy Specifications the acid tests do not apply to the enamel in the interior for that conduit which has a protective zinc coating beneath. This allows a very thin enamel to be used by those manufacturers who apply zinc to the interior wall while a good grade giving a heavy film must be used by others. This somewhat equalizes the costs.

The coatings used in the interior of conduit cover a wide range. The colored wash in the hot galvanized and clear enamel in the sherardized have been mentioned. Electro-galvanizers use a black enamel except one who uses a red iron oxide enamel paint which is of an excellent quality.

To enamel or paint the interior of conduit requires a special apparatus. A tank similar to the one used for black pipe is used. The pipes are let down into this on racks. The enamel is stored in a small tank about 10 to 15 ft. above. A circular spraying nozzle is let into the top of the pipe. A valve allows the enamel to flow and the head of enamel sprays it on the interior wall of the conduit. Enough is introduced to thoroughly cover the entire interior surface. The surplus drains to the bottom of the tank from where it is pumped back to the storage tank to be used again. This method of enameling is very effective and one man can work at the rate of 600 lengths of pipe per hour. The remaining procedure is similar to that of the black pipe.

Enameled or painted "white pipe" is now sold extensively. The enameling of this pipe does not present any difficulties beyond those found with the black pipe. The applying of a paint presents difficulties of a different nature. The pigments used settle quickly and some method must be devised to keep it evenly distributed throughout the oil. The stirring may be accomplished by means of a propeller. Even with stirring the conduit will not be evenly coated by the pigments. The more practical way of applying the paint would be by means of a spray. In this way the pigment would be more evenly distributed and not be washed away as it is when the conduit is withdrawn from the tank.

When sherardized pipe was paraffined the following method was used. A solution of paraffine of the requisite strength was made in warm benzine. This solution was contained in a horizontal tank capable of holding 5000 ft. of $\frac{1}{2}$ -in. conduit. Steam coils kept the solution hot to prevent the paraffine from freezing out. About 5000 ft. of $\frac{1}{2}$ -in. pipe, after enameling the interior, were dipped into this tank in one bundle. Any superfluous dust was washed off and settled to the bottom while a thin layer of paraffine remained on the pipe after the benzine had evaporated.

After the conduit has been galvanized and enameled it is inspected, labeled, banded and is ready for shipment.

Black Pipe versus White Pipe

At present the relative merits of the various brands of white pipe are subject to a large amount of controversy. The "black pipe" has been almost entirely neglected, it being generally taken for granted that it is an inferior conduit. Large numbers of tests of galvanized pipe have been made both by partial and impartial investigators and the results made by the former are contradictory while those made by the latter agree fairly well.

If the "man on the job" were asked what pipe he would prefer there would be but one answer which would be "black pipe." He prefers it because of its clean, smooth surface, superior appearance, excellent fishing qualities and because it "takes" paint. He objects to the rough surface of the electro-galvanized because of the "acid" which he says eats into his skin. He objects to the hot galvanized pipe because of its rough surface and some even complain of the "acid." The sherardized paraffine finished pipe was objectionable because of the paraffine finish which became soft in warm weather. Without the paraffine the conduit was dusty.

The stiff competition in conduit manufacture has raised the standard to a high plane. Where, about six or seven years ago, most any kind of enameled pipe would have been acceptable, now this is no longer true and a good quality has to be made. By way of confirmation, one only needs to look at conduit installations of a few years ago and compare them with those of to-day.

As stated above the durability of the different kinds of "white pipe" has been the subject of much argument. The relative merits of black and galvanized pipe are not often mentioned and the writer wishes to emphasize the high merit of the former. Each class of pipe is best under certain conditions and before an installation is made these should be studied to obtain the greatest service per unit of cost.

Conduit is subject to a wide range of conditions. Outdoors it is subject to the action of the weather; it may be buried and here a variety of conditions may affect it, ranging from a dry to a wet, acid soil; it is subject to temperature extremes; it may be buried in cement, cinder, concrete or various plasters; it may be exposed to corrosive vapors, coal smoke, or gases; it may be attacked by oils, acids or alkalis, and it is always subject to mechanical injury in transportation during installation and sometimes in service.

Prof. C. F. Burgess¹ has shown that a high grade enameled conduit, the surface of which has not been injured, is superior to galvanized conduit under a variety of corrosive conditions. Those cases coming under the writer's observation have confirmed this, but only where a good grade of enamel was used. Any enamel that conforms to the Navy Specifications as given above must be resistant to corrosive influences.

But under ordinary conditions of shipment and installation the exterior enamel is scratched and scraped, exposing the iron beneath and subjecting it to corrosion. This condition is necessarily important when comparing with galvanized conduit.

Under the following conditions enameled pipe is cheaper to install and will be fully as satisfactory as the galvanized. In room interiors where the conduit is afterward painted, under similar outdoor conditions, in walls of buildings including bath plastered and concrete where moisture is not present; in short, any place where dry conditions prevail and any exposed iron is not subject to permanent corrosive conditions. This would cover a large percentage of installations.

By painting the enameled pipe after installation it could be made superior to non-enameled galvanized conduit under many conditions. Where the latter is installed and is exposed to acids and fumes the galvanizing soon is corroded. The resistance of unscarred enameled pipe to such conditions has been pointed out by Prof. C. F. Burgess.² By giving the scarred places a coat of slow air drying enamel after installation, the conduit could be made comparatively permanent.

Under exposure to alkalis there would be an advantage to the galvanized conduit but under such conditions even the latter

¹Sherardizing Magazine

shows a high rate of corrosion and brass, lead, or composition conduit are necessary. Under conditions where the application of this enamel after installation would be impractical or under peculiar conditions of exposure where the enamel would blister and peel the galvanized conduit would be better suited.

The importance of securing as permanent an installation as possible in modern buildings even at a much higher cost has been recognized by some engineers and architects. These men have specified conduit that is both galvanized and enameled, and, so insistent has been this demand, that manufacturers are turning out this class of conduit.

The importance of such a protecting coat over the galvanizing was first noticed in the testing of the paraffined sherardized pipe. The paraffine was primarily used for laying the dust but at the same time it increased the resistance to corrosion to a remarkable degree. It seems as though this increase in the life of the sherardizing would have been the important feature but was not recognized as such by the manufacturers. Tests^{2,3} on paraffined and non-paraffined conduit showed the marked superiority of the former, being fully as durable as the enameled conduit.

The writer believes that any enamel that is used over the galvanizing should be equal in quality to that used on "black pipe." A cheap enamel will soon disintegrate and leave the galvanizing exposed. And where such a conduit is installed the scarring of the enamel during installing will make it little better than the raw galvanized material. The painting of all scars is very important and should be rigidly enforced if the maximum of service is to be received.

The U. S. Government has recognized the value of such a double protection, especially on war vessels, and along the Panama canal, where galvanized conduit, usually sherardized, is painted after installing and is repainted regularly.

The value of the different galvanized coatings when used for conduit protection is a much discussed subject. With the constantly improving methods and with the new brands continually appearing, no data are ever complete.

Some of the earliest work was done by Prof. C. F. Burgess³ at the Chemical Engineering Laboratories of the University of Wisconsin and showed the relative merits of hot, cold and dry galvanized and enameled conduit. Messrs. Leighou and Calderwood⁴ of the Carnegie Technical Schools made some exhaustive tests in 1912 of the value of electro-galvanizing and sherardizing as a protection for conduit purposes.

The value of galvanizing is usually determined primarily by the amount of zinc per unit of area. The other important factors are homogeneity, purity, continuity and tenacity with which it clings to the iron.

The cold galvanized conduit is made by several manufacturers and the product varies. The first of such conduit showed up poorly under actual service conditions as well as in accelerated tests. This was the result of the light deposit of zinc and its uneven distribution. The threads and couplings were usually subject to immediate corrosion owing to the absence of zinc. The amount of zinc has been materially increased but even now the threads and couplings rust quickly. The writer has under his direct observation a large amount of cold galvanized conduit of recent installation and every length is badly rusted at the joints.

The copper flashed conduit employing a thin zinc deposit has shown no superiority over the ordinary electro-galvanizing under actual service conditions.

The sherardized conduit has been subject to many tests and has shown that when the alloy is formed under proper conditions it results in a coating that is superior to the electro-galvanized or hot galvanized material. The present practice of sherardizing shows a lack of uniformity of practice and results obtained. The theoretical alloy that should be obtained is one corresponding to FeZn_{10} , containing about 8 per cent of iron. Where this alloy has been obtained a coating highly resistant to corrosive action has resulted. The writer's experience has shown that a low temperature is necessary for the production of such an alloy, probably lower than any temperature

used in commercial sherardizing plants of today with but one or two exceptions.

With the increase of iron content of the coating the more quickly will it corrode. With coatings containing from 25 to 30 per cent of iron the writer has found that the sherardizing affords little protection since it pits easily. Such a coating is obtained by using high temperatures and a lean zinc dust.

A peculiar property of this alloy is the formation of a blue black covering after being exposed to the weather for some time. Cushman⁵ calls attention to the highly protective powers of sherardizing, through its ability to take on this highly resistant black coating, which he explains as being the formation of Fe_3O_4 from the oxidation of the iron in the alloy. He states that this oxide will greatly increase the life of the coating owing to its superior weathering qualities. This black appearance is especially found on exposed paraffined conduit.

The successful introduction of the hot galvanized conduit is of great importance since it is almost impossible to obtain a thin coating with this process. This conduit should, if the weight of coating and other factors are considered, have a long life. Hot galvanized pipe stands high in corrosion tests.⁶ What effect the introduction of aluminium will have can only be conjectured.

The importance of the interior galvanizing is often over-estimated. In most cases few fumes and vapors come in contact with the interior and a coat of good enamel should be sufficient to protect against all corrosive influences.

The testing of galvanized conduit is usually done by the standard Preece copper sulphate method and the coats are usually spoken of as being so many "dips" in thickness.

The writer has tested the Preece method and has found that it is very reliable, cheap, and entirely satisfactory as a quick factory method for testing galvanized conduit. The heaviness of the coating is a straight line function of the number of dips and makes the factory control very simple.

But results obtained by this method on two different types of galvanizing are not comparable. It will be found that sherardizing of the same weight as electro-galvanizing will give twice the number of dips in copper sulphate.

The writer has often heard the statement that a coating standing one dip will be equal to three years of atmospheric corrosion. On the strength of the copper sulphate tests resulting from the above statement, a large amount of conduit has been sold. Some manufacturers, quickly realizing that the addition of certain materials to the coating would raise the Preece test without materially increasing the coat, began this practice. As a result of this the test when used by the salesman is practically worthless.

To arrive at a fair basis, depending upon the actual amount of zinc present, a new method has been proposed.⁷ In this method the zinc or zinc iron alloy is removed by basic lead acetate. This method is very satisfactory where an accurate determination is desired and in the comparison of two unlike conduits. For routine factory testing it is not practicable since it involves several weighings with the balance. It may be used in occasionally checking up the copper sulphate tests. The actual amount of zinc present will not be indicative of the serviceability of the conduit for this will depend on the process.

From this description of the making of rigid conduit after leaving the tube mill the process is seen to be a product of the chemical engineer and electrochemist. Unfortunately they have not been instrumental in the early development of the processes that have only received their aid during the past decade.

How long the galvanized conduit will be supreme is a question of when some other cheap resistant coating may be applied to iron or some other resistant metal or alloy may be produced cheaply enough to compete with steel. The possibility of using a lead coating instead of zinc is an attractive proposition. Samples of such conduit have come to the notice of the writer from time to time and to all appearances should make an excellent conduit.

Chemical Engineering Laboratories, University of Wisconsin,

The Determination of Vanadium in Ferro-Vanadium

By Wm. W. Clark

As all ferro-vanadium is sold on a basis of the vanadium content, the determination of vanadium is the most important one in the analysis of the alloy. It is not a difficult determination, but is one that is easily influenced by conditions, and consequently very few analysts get correct results by a few tenths of a per cent.

A number of methods have been introduced for the determination, which when run on pure salt, give fairly concordant results, but when an alloy of indefinite composition is encountered, the chances of error multiply, or if the vanadium is separated from the other metals present, considerable time is wasted, with corresponding losses of vanadium in the separation. The majority of the methods depend upon the oxidation of the vanadium from the vanadyl to the vanadic salt or vice versa. Some of these methods are indirect, such as the reduction of the vanadic salt to the vanadyl, with hydrochloric, hydroiodic, or hydrobromic acid and the absorption of the evolved chlorine, iodine or bromine in potassium iodide, and subsequent titration of the liberated, or absorbed iodine with sodium thiosulphate solution. These methods are erratic on account of the reduction not stopping at a specified compound, some of the vanadium going to a lower valency, with the liberation of the corresponding amount of the halogen.

The method which seems to be in general use is the separation of the vanadium from the metals by means of sodium hydrate, reduction of the acidified filtrate with sulphur dioxide, removal of the excess sulphur dioxide by boiling and a current of carbon dioxide, and subsequent oxidation of the reduced vanadium with potassium permanganate. This method, while theoretically correct, gives results which as a rule are high, if the vanadium is all separated from the precipitate of iron. It requires two or more separations to get all the vanadium out of the bulky iron precipitate, and the filtrate must be boiled and refiltered on a very close filter as some iron always goes through on the first filtration. The method is slow, taking not less than four hours for a single determination, and most all of the operator's time. It takes several filtrations, which we try to avoid as much as possible, as they take time and introduce errors. The method in detail is as follows:

A factor weight of the finely powdered alloy is dissolved in sulphuric and nitric acids, evaporated to white fumes of sulphuric anhydride, diluted, and the iron precipitated by pouring the nearly neutralized solution into an excess of boiling sodium hydrate, which contains a small amount of sodium peroxide. Sodium should always be used when separating vanadium, as sodium vanadate is more soluble than the potassium salt. The solution is boiled and filtered. The precipitate is dissolved in hot sulphuric acid and reprecipitated. The combined filtrates boiled, again filtered on a close filter, acidified with sulphuric acid, adding about 10 per cent excess, reduced with purified sulphur dioxide, the excess of which is removed by boiling and the passage of a current of carbon dioxide, which has been passed through a solution of sodium carbonate. The gas is passed until the steam will not discolor a solution made slightly pink with a drop of permanganate. The vanadium is then oxidized with N/10 potassium permanganate, titrating to a pink in the hot solution.

Following are typical results on three different vanadium compounds: a pure solution of vanadium, a synthetic solution made of approximately the same composition as a solution of an alloy, and a standard ferro-vanadium. The pure solution was made from pure vanadium pentoxide, which was made by recrystallizing ammonium vanadate several times. The salt was dried and the major portion of the ammonia driven off in a drying oven. The oxide was then melted in a platinum dish in a current of oxygen. The resulting oxide was ground to a fine powder and showed the following composition by analysis:

Vanadium	55.06%
Vanadium Pentoxide	99.86

Vanadium Tetroxide	0.70
Ammonia	0.00
Sodium Oxide	0.948
Silica	0.063
Alumina	0.041
Alkaline earths	0.06
Hydrogen sulphide metals	0.00
Iron group	0.009

A weighed amount of this oxide was fused with pure sodium carbonate, the water solution acidified with sulphuric acid, and diluted to a definite volume, 1 c.c. of which contained .003136 grams vanadium. The synthetic solution was made from this solution, and C. P. salts. The standard ferro-vanadium has been carefully analyzed and the results averaged. Fifty c.c. of the pure solution was taken in each case, this being equal to a percentage of 30.74 vanadium on a factor weight of alloy.

Pure solution	Synthetic solution	Standard
Vanadium present.	Vanadium present.	Ferro-Vanadium
30.74%	30.74%	Vanadium present
Vanadium found.	Vanadium found.	Vanadium found
30.68%	30.82%	35.56%
30.74	30.92	35.86
30.78	30.88	35.74
30.70	30.82	35.88
30.78	30.90	35.72
Average results	Average results	Average results
30.74	30.88	35.70

The pure solution gives very good results, but the synthetic solution and the standard ferro-vanadium show an increase of 0.14 per cent and 0.24 per cent respectively. This increase of vanadium has always been found, and if the work is very carefully done, keeping all conditions constant, the results will keep down between 0.10 per cent and 0.30 per cent high, but at the present price of ferro-vanadium this is too great an error. It has been noticed that often when no more sulphur dioxide can be detected in any way, the results will run several per cent high. This has not been accounted for, except on the theory that some product is formed in the solution which is oxidized by permanganate, nor has the cause of the ordinary high results been determined. Of course this method cannot be used when metals reducible by sulphur dioxide are present, as they will again be oxidized by the permanganate with the vanadium.

All the other methods, which were at all practical, were tried in the same manner, and discarded for very much the same reasons as the above method.

The following method has been found to be accurate under all conditions, and on all varieties of work. The solutions needed are:

N/10 potassium bichromate, made by dissolving 4.008 grams of the pure salt per liter of water, and carefully standardizing to exactly N/10 at 20 deg. C. against pure iron wire, and also against N/10 potassium permanganate which has been standardized at 20 deg. C. against sodium oxalate, procured from the Bureau of Standards. Ferrous ammonium sulphate was used as an intermediate solution. The bichromate is constant and needs very little care after it is standardized, except that it should be restandardized once a week to guard against accidents.

N to ferrous ammonium sulphate solution, made by dissolving 40 grams of the salt per liter of 10 per cent sulphuric acid. As the strength of this solution changes about .004 c.c. per c.c. a day, it is standardized against the bichromate under working conditions every day.

A blank of 0.32 grams pure iron is run the same as a test to the point of titration, when 35 c.c. of the ferrous solution is added. This is titrated back with the bichromate to a definite end point. For instance 35 c.c. of the ferrous solution took 34.20 c.c. of the bichromate to oxidize it. This shows the ferrous solution to be 0.80 c.c. weak in 35 c.c., or 0.023 c.c. per c.c.

This factor is subtracted for each c.c. used on a determina-

tion, or if the ferrous solution is strong, the factor is added.

Potassium-ferri-cyanide solution made by taking a piece of the salt about the size of a pea, and washing the outside several times with pure distilled water to remove any ferro-cyanide which may have been formed on the outside, and dissolving the remainder in 50 c.c. distilled water. The ferri-cyanide must contain no ferro-cyanide, as vanadyl salts gives a green precipitate with ferro-cyanide and this can easily be mistaken for the green of the ferrous iron. A paper appeared some time ago (Cain, J., *Ind. & Eng. Chem.*, Vol. III, 476), claiming that vanadyl salts in acid solution, reduced ferri-cyanide to ferro-cyanide, thus giving erratic results. This has been tried from every angle on pure salts and under working conditions, and no immediate action could be noticed. Fifty c.c. of a 10 per cent solution of vanadyl sulphate was added to 50 c.c. of a 1 per cent solution of ferri-cyanide, and allowed to stand for twenty-four hours. No precipitate had formed at the end of that time, while when one drop of a 1 per cent solution of ferri-cyanide was added to the mixture, a light green precipitate developed in a few minutes. The presence and amount of ferro-cyanide in ferri-cyanide can very easily be determined by means of this reaction. Care must be taken not to make the ferri-cyanide solution too strong as the yellow color will mask the last traces of green in the spot.

Potassium permanganate solution, made approximately N/10 but not standardized.

Sulphuric acid—one part acid to two parts water. This strength acid is used, as it can be poured into hot fuming sulphuric acid without spattering, saving considerable time cooling and again heating the solution.

The apparatus used is an automatic burette, for the ferrous ammonium sulphate solution, made from our specifications by Bausch and Lomb. The burette is made to deliver 50 c.c. and is graduated in 1/20 c.c. from 30 c.c. to 50 c.c. A 25 c.c. burette graduated to 1/20 c.c. is used for the bichromate and an ordinary 50 c.c. burette for the permanganate. A white porcelain spot plate can be used. The depressions should be shallow as it is easier to control the spot in a shallow one. They are cleaned by dropping into a sodium hydrate solution after using, and then washing. The best spot is shown on a piece of waxed dead white, high gloss cardboard. The card is cut to size and immersed in a solution of white paraffine, repeating until the coat of wax is heavy enough to keep the solution from coming in contact with the paper.

The drop remains spherical and reflects the smallest traces of green. The waxed cards are easier to handle than the plates, and after being used are thrown away. The ferri-cyanide is kept in a flat top dropping bottle, which regulates the size of the drop.

The method is as follows:

Dissolve a factor weight (0.510 grams) of the finely powdered alloy in 25 c.c. of the dilute sulphuric acid and 10 c.c. concentrated nitric acid, and evaporate to white fumes of sulphuric anhydride. If the alloy is refractory to these acids, it is transferred to a platinum beaker with the addition of 20 c.c. hydrofluoric acid, and again evaporated to white fumes. Seventy-five c.c. of the dilute sulphuric acid is added to the hot fuming mass and the solution heated until all the salts have gone into solution, when it is boiled for two minutes. The solution is transferred to a 5-in. white porcelain casserole. 75 c.c. more of the sulphuric acid added, and hot water until the bulk of the solution is from 400 to 500 c.c. The solution is then heated to above 65 deg. C. Potassium permanganate is added from the burette to a deep red. This red is just discharged with the ferrous solution, then permanganate is added drop by drop until the last drop just gives a pinkish tinge to the solution, which is discharged by one drop of the ferrous solution. The ferrous sulphate burette is now filled to O, and an excess is run into the solution, this excess is shown by the ferri-cyanide spot. An excess of at least 2 c.c. should always be added. This excess is titrated back with the bichromate solution being careful to come to the same end point as in the blank. The c.c. of the ferrous sulphate solution

used, plus or minus the correction, less the c.c. of bichromate solution used to oxidize the excess of the ferrous solution, gives the percentage of the vanadium in the alloy directly.

The only points to be carefully watched are the neutralization with the ferrous and permanganate solutions, the end point with the ferri-cyanide spot, the variation of the strength of the ferrous ammonium sulphate solution, and the temperature of the solution while being titrated.

The neutralization point can be caught within 1/20 c.c. after a little practice. The operator can alternate drop for drop of the two solutions as long as he is uncertain as to the exact point, without impairing the accuracy of the determination in the least. An alternate method can be used for this neutralization as follows: The alloy is dissolved in 25 c.c. of the sulphuric and 10 c.c. nitric acid, evaporated to white fumes, the salts dissolved in hot water, and diluted to 500 c.c. Potassium permanganate is added in excess, and the solution boiled until all permanganate is decomposed, or a crystal of manganous sulphate can be added to hasten the decomposition. The precipitated manganic oxide is filtered on a tight asbestos plug, using suction. The filtrate is boiled, and if any precipitate comes down, it is again filtered. The solution is now evaporated to a convenient bulk (about 300 c.c.), 150 c.c. of the dilute sulphuric acid added, the solution heated to above 65 deg. C., and an excess of ferrous solution added directly. This method gives good results, provided all the manganic oxide is removed by filtration, but takes at least an hour longer than the regular method.

The end point with the ferri-cyanide is very easily seen, and if the operator bears in mind the color of the end point on the blank, and on the standardization, and always titrates to that point he will get good results. No two operators see the end point the same, so they must use their own standardization, and blank. If the end point is over titrated more ferrous solution can be added and again titrated back with bichromate.

The temperature of the solution must be kept above 65 deg. C. or the results will be low. Tests run at different temperatures show that the amount of ferrous solution oxidized by the vanadium decreases with the temperature, running as low as .60 c.c. in the cold, but it makes no apparent difference how far the temperature is raised above 65 deg. C.

The above method is fast, taking about 30 minutes for a single determination, does not vary when other metals are present, chromium being the only interfering element, and its interference can be eliminated by getting the neutralization point between the ferrous and permanganate solutions in the cold, and then heating to above 65 deg. C. for the titration. The presence of chromium can be shown with an acetic acid solution of diphenylcarbazide, this reagent being very sensitive to chromium.

Each and every determination of vanadium made on ferro-vanadium is run in duplicate, and not once in a hundred times is there a difference of more than 0.10 per cent.

The following results obtained on regular routine work, show how the method runs.

		Standard
Pure solution	Synthetic solution	Ferro-Vanadium
Vanadium present.	Vanadium present.	Vanadium present.
30.74%	30.74%	35.56%
Vanadium found.	Vanadium found.	Vanadium found.

Spelter Production in 1912

The Geological Survey has just issued its advance statement of spelter production and consumption in 1912. This statement gives the final figures of output by the zinc smelters for the year, distributed both by states producing the ore and by states in which the ore was smelted, thus giving a measure of the zinc mining industry as well as the zinc smelting industry. The zinc ore made into pigments is not included in this statement, hence the full extent of the zinc mining industry is not covered. The imports and exports of spelter, zinc dross and zinc ore are also given, as well as a list of smelters and their capacity, revised to the close of 1912, together with additions being built during the first months of 1913. A long chart shows graphically the fluctuations for the last seven years in the price of spelter at St. Louis and London, and in the price of 60 per cent zinc concentrates at Joplin.

The production in the United States of spelter made from ore, both domestic and foreign, was 338,806 short tons, an increase of 52,280 tons, or 18.2 per cent, over that of the previous year, and by far the largest output in the history of the industry. The final figures show that the Survey's estimate of production given out January 2, 1913, was too low by only 176 tons, or 0.05 per cent. The spelter made in the United States from foreign ore in 1912 amounted to 14,809 tons, almost exactly the same as in 1911, and considerably less than in 1910 and several preceding years. The production of spelter from secondary sources such as skimmings and drosses also made large gains, being estimated at 50,000 tons, of which 21,000 tons was redistilled, partly at regular zinc smelters using ore and partly at plants devoted exclusively to the redistillation of secondary materials.

The consumption in the United States of spelter made from ore was 340,372 tons, an increase of 60,313 tons, or 21.5 per cent, over that of the previous year. The increase in consumption was made possible by the large imports of spelter. For the last four months of the year the average St. Louis price of spelter was more than 1½ cents above the London price. It was during this period that the larger part of the 11,115 tons of foreign spelter was imported.

The list of smelters shows a total capacity of 107,948 retorts at the close of 1912, with additions of 12,216 retorts under construction. With the exception of 576 retorts, the additions are all in Illinois. It should be borne in mind that all this capacity will not be effective for smelting ore, for several of the plants listed are devoted partly or exclusively to the recovery of spelter from secondary materials.

An aluminium solder has been patented by Richard Seitter, of Union Hill, N. J., consisting of 38 per cent pure tin, 32 per cent phosphor-tin and 30 per cent pure zinc. It is claimed that this solder will be effective in joining pieces of aluminium, or pieces of brass or bronze with aluminium.

Electrolytic Production of Iron Sheets and Tubes, Etc.

By Wilhelm Palmær and J. A. Brinell

Upon request of the directors of Jernkontoret (the Swedish Iron Masters' Association) the authors have made a study of the S. Cowper-Coles electrolytic method for producing iron sheets and tubes, etc., at the inventor's laboratories in London. The results are given in the following paper. For the purpose of investigating the quality of the products, the composition of the electrolyte and other matters, tests have been made at the testing laboratories of the Royal Technological Institute at Stockholm, the results of which tests also will be given in the following.

The inventor has described his method in a lecture: "The Production of Finished Iron Sheets and Tubes in One Operation," delivered at a meeting of the Iron and Steel Institute at Middlesbrough in 1908, published in the *Journal of the Iron and Steel Institute* and in *Electrochemical and Metallurgical Industry*, November, 1908, vol. VI, p. 447, and he has also received a number of patents.*

Before entering into the description of Cowper-Coles' process we wish to call attention to the fact that electrolytic refining of iron has been subject of much research work, partly for practical purposes. In the above-mentioned lecture Cowper-Cowles reviewed some of this work, a more complete synopsis of which will be found in a recently published book by F. Foerster¹ and in a bibliography written by A. Müller.² As yet it seems that electrolytic refining has found practical use only for electroplating purposes, such as steel plating of copper engravings for printing of bank notes at the Imperial mint at St. Petersburg, Russia, where such a plant has been used since 1860. It seems that the Langbein-Pfanhauser Werke Aktiengesellschaft, Leipzig-Sellerhausen, Germany, has lately been working along the same lines as Cowper-Coles, on a method suggested by F. Fisher.³

Principles of the Method

The Cowper-Coles method is an electrolytic refining process. From pig iron he produces iron sheets or tubes of nearly pure iron. The principles of the method are therefore identical with those of other commercial electrolytic refining processes for the purpose of producing pure copper in ingots, sheets and tubes, as well as silver, gold, zinc, nickel and lead in pure quality. The pig iron is used as anode in a solution of an iron salt. On the application of direct current pure iron is deposited on the cathode, while at the same time a corresponding amount of iron is dissolved from the pig iron anode so that the composition of the solution remains unchanged.

The difficulties to be overcome in the development of such a method are mainly following:

(1) A salt solution must be found suitable as electrolyte, with a sufficiently high conductivity and one which is not fouled too rapidly.

(2) Beside the nature of the electrolyte, the voltage and current density must be correctly chosen in order to get a pure dense deposit in form of an even sheet or ingot without spongy formations and without the actual energy consumption exceeding the theoretical requirement to any appreciable extent.

(3) Electrolytic refining is easier with comparatively pure metals such as copper, silver or gold, than with more impure metals such as iron and zinc, since in the latter case hydrogen will be evolved at the cathode as easily as metal deposited.

The electrolyte used by Cowper-Coles is a concentrated solution of ferrous chloride, containing also iron salts of certain organic acids and an amount of iron oxide is added to give a consistency of a gruel. Additional organic compounds are also used to produce more satisfactory results. The organic acid,

of which the iron salt is contained in the solution, is according to a statement in the inventor's former lecture, $\text{CH}_3(\text{OH})\text{C}_6\text{H}_4\text{SO}_3\text{OH}$, consisting of several isomeric cresol-sulphonic acids. The additional iron oxide is intermingled for the purpose of reducing the acidity and polishing the iron sheet which is deposited on a rapidly rotating cathode. The anode used by Cowper-Coles consists of pig iron.

It might be expected that nearly pure iron would be deposited—that is soft sheet iron without carbon or impurities. There is, however, in fact some carbon in the iron obtained by the

of the latter, the thinnest sheets, can most easily be produced.

As to the application of the process for the far more important problem of producing iron of highest purity and quality from ore, it seems that this has been only slightly studied by the inventor, and we shall briefly return to this subject later.

Construction of the Electrolytic Cell

A sketch of the electrolytic cell used at the experimental plant at 20 Danvers street, Chelsea, London, is shown in Fig. 1. The illustration is made partly from sketches and dimensions taken by the authors and partly from a drawing furnished by the inventor. It is drawn at a scale of 1:8, the dimensions being in millimeters.

B is a tank of riveted 5-mm sheet iron containing the electrolyte. Its height is 310 mm and it consists of two concentric cylinders with a bottom. In the horizontal cross section the outer and inner circles show the walls of the tank. On the inside of the tank walls is applied a heavy coating of insulating paint which is of great importance as they otherwise would serve as an anode and rapidly be corroded.

At the inside of the outer wall there are three iron anodes, *A*. They are each 300 mm long and 12 mm thick and are made of curved pig-iron plates, each covering about 1/12 of the circumference. The anodes are separated from the tank through an insulating material, *I*. As will be noted the anodes cover together only about one-quarter of the surface of the tank.

The cathode proper, *K* consists of a 0.5-mm. copper-plated iron cylinder, which is placed outside another cylinder, *C*, of heavier sheet iron (perhaps 5 mm.). The upper and lower edges of the cathode, *K*, are turned out slightly and the space filled with asphalt, probably for the purpose of preventing iron to deposit there. The height of the cathode, *K*, is about 185 mm and its diameter is about 275 mm. The space between cathode and anode is about 40 mm.

The cylinder, *C*, serves as a conductor to *K* and also to support the cathode in such a way as to allow a rapid rotation.

For the latter purpose, the cylinder, *C*, with its sheet-iron cover, *H*, is connected with a vertical steel axle, *E*, supported by bearings *S* and *D*. Through the belt, *R*, the cylinder, *C*, and the cathode, *K*, are rapidly rotated. The shaft, *E*, has just above the pulley a ring attachment, *U*, which during the rotation of the shaft is partly submerged in a bowl filled with mercury, which bowl is not connected to the shaft. The mercury is connected to the negative busbar and transmits current to the rotating cathode *K*.

Finally there is under the tank a circular gas burner for the heating of the electrolyte.

Experiments Performed at the Authors' Visit

The electrolyte used on this occasion was, according to a statement by the inventor, prepared as follows:

Concentrated hydrochloric acid (sp. gr. 1.17), mixed with the cresol-sulphonic acids mentioned before, is heated with a large amount of scrap iron, which is dissolved, while developing hydrogen, until the solution is saturated with iron. The solution, the specific gravity of which has increased as a result of the solution of the iron, is diluted until the specific gravity is 1.4, after which, even on cooling to ordinary temperature no iron salt (ferrous chloride) crystallizes out. The solution contains then about 40 per cent ferrous chloride (FeCl_2) to which are added before using about 300 grams of ferric oxide (Fe_2O_3) per liter, so that it gets about the consistency of gruel.

The addition of this ferric oxide is primarily made for the purpose of reducing the acidity of the solution as far as possible, with proper consideration given to the hydrolysis of the iron salt solution. Moreover, the ferric oxide affects the condition of the finished product. As mentioned before, since the cathode is rapidly rotated and through friction with the iron oxide, the sheet or tube deposited on the cathode receives a high finish. In the Elmore process for the electrolytic production of copper tubes the finish is obtained by means of polishing slate of agate applied under pressure and moved up and down in the longitudinal direction of the tube, while in the Cowper-Coles process the same result is obtained by rapid rotation with accompanying friction with the liquid.

FIG. 1—CONSTRUCTION OF ELECTROLYTIC CELL

Cowper-Coles process and there are also traces of phosphorus and sulphur.

That carbon can be electrolytically deposited to a small extent, has been stated,* but without endeavoring to control the percentage of carbon, one should be satisfied that the product will always be a soft sheet metal of very high quality. It is also likely that the carbon, which is found by analysis, is due to slime mechanically transported from the anode to the cathode.

According to Foerster (p. 77 of his book) consideration should also be given to the colloidal organic substances which may be deposited on the cathode, as a result of the oxidation of carbon of the pig-iron anode.

On the other hand the electrolytic process has the advantage over the rolling process that the most expensive product

* *Zeitschrift f. Electrochemie* 1896, 2, 541

Experts have testified that an iron sheet produced in a solution containing iron oxide is solid while a sheet produced under other circumstances is perforated by numerous small holes.

The information given by the inventor in regard to the composition of the electrolyte is confirmed by the analysis we have had made at the Material Testing Laboratories of the Stockholm Royal Technical Institute of samples of the solution taken immediately before and after the electrolysis. These tests are referred to as I and II respectively. At first the solution was tested with the ferric oxide contained in it.

	I.	II.
	Before	After
	Electrolysis	
Specific gravity	1.60	1.67
Amount of slime in grams per liter:		
Dried at 105 deg. C.....	245	293
Heated to glowing.....	240	288

The percentage of slime is found to be somewhat different with the amount of stirring at the different times when the samples were taken. Due to the same fact the specific gravity varied somewhat.

Subsequently the filtered solution was analyzed. In both samples it had a light green color, showed a weak acid reaction, and had an evident smell of carbonic acid (phenol).

The result of the analysis is as follows:

	I.—BEFORE		II.—AFTER	
	Grams per Cu.Cm.	Per Cent Weight	Grams Per Cu.Cm.	Per Cent Weight
Specific gravity of solution at 150° C.....	1.46		1.46	
Bivalent iron	0.235	16.1	0.235	16.1
Trivalent iron	Trace		Trace	
Sulphur as SO ₃	0.0189	1.29	0.0223	1.53
Chlorine	0.290	19.9	0.285	19.5
Ferrous chloride, Fe Cl ₂ , calculated from quantity of chlorine	0.518	35.5	0.510	35.0
Cresol-sulphonic acid, corresponding to the quantity of SO ₃	0.0445	3.0	0.0524	3.6

The small differences in the analysis should be considered as experimental errors and we conclude that no difference in the composition before and after electrolysis has been established. This was not unexpected, since the time of electrolysis was only two hours.

The amounts of FeCl₂ and cresol-sulphonic acid correspond approximately to the figures given by the inventor.

For the purpose of comparing the energy consumption and voltage of the Cowper-Coles process with that used in other electrolytic refining processes, it was of interest to investigate the conductivity of the electrolyte used. The result is stated below, the conductivity, *C*, being the reciprocal of the resistance, in ohms, of a column of 1 cm length and 1 sq. cm cross section. For comparison we have given some results of measurements of the ordinary electrolyte for copper refining (1 normal CuSO₄ + 1 normal H₂SO₄).

Cowper-Coles Electrolyte		Copper Electrolyte	
Temperature	C.	Temperature	C.
100 deg. C.	0.213	101 deg. C.	0.270
13 deg. C.	0.0506	42 deg. C.	0.231
		13.8 deg. C.	0.170
		0 deg. C.	0.144

According to these and other measurements the conductivity of the Cowper-Coles solution at 100 deg. C decreases 0.88 per cent per degree.

For the experimental temperature of 92 deg. C. of Cowper-Coles solution $C = 0.198$ and if corrected for the ferric oxide which occupies in volume 58 cu. cm per liter and which is a non-conductor of electricity $C = 0.187$.

In copper refining ordinary or somewhat raised temperatures (45 deg. C.) are used and it seems that at these temperatures the conductivity of the solution is about 0.2 that is nearly the same value as above. The voltage for copper refining is stated

to be 0.25 volt to 0.4 volt, while in the Cowper-Coles process it is about 1.4 volt. This great difference in voltage is not due to the lower conductivity of the Cowper-Coles solution but as calculation shows is due to the greater current density and the greater distance between the electrodes, while the anode surface is smaller than the cathode surface. It may be mentioned that in electrolytic silver refining a still higher voltage is used, namely, 2 volts to 2.5 volts.

The volume of the electrolyte used at our visit may be estimated at about 15 liters.

In calculating the current or current density, the surface of the cathode was taken as 16 sq. dm. as given in the description of the electrolyzer. The voltage varied in electrolysis I between 1.25 and 1.45 volt according to the temperature, the voltage decreasing as the temperature increased. The temperature was read a number of times and varied in electrolysis I between 88 deg. C. and 94 deg. C.

The speed of rotation at the cathode varied in electrolysis I between 108 and 160 revolutions per minute.

In calculating the efficiency it has been assumed that one ampere will deposit 0.0174 gram of iron per minute from the solution of ferrous salts, there being no appreciable amount of ferric salts.

Electrolysis I

In the first electrolysis a cylinder of thin copper-plated sheet iron was used as cathode. To loosen the electrolytically deposited sheet the cathode cylinder had to be heated until glowing.

The electrolysis was carried out for 2 hours, 2.5 min.
Average current 107.9 amp.
Current density at cathode..... 6.74 amp. per sq. dm.
Average voltage 1.34 volt
Average temperature 92 deg. C.

The average speed of the rotating cathode was 130 r.p.m., corresponding to a peripheral speed of 120 meters per minute.

Efficiency.—After heating the cathode in a reducing atmosphere, whereby deposited hydrogen was also removed, the iron sheet could be removed from the cathode and weighed. It was soft and had a thickness of about 0.15 mm. Its weight was 102 grams, not including some pieces which had fallen off nor the iron deposited on the cylinder C. This amount (102 grams) corresponds to an efficiency of 83.5 per cent, assuming that 230 grams could be deposited by the number of ampere-hours used.

In order to account for the total ampere-hours.

the iron sheet produced corresponds to..... 83.5 per cent
Hydrogen evolved corresponds to..... 11.8 per cent
Iron lost and deposited on cylinder C, escaped

hydrogen, errors in test, corresponds to . . . 4.7 per cent

100.0 per cent

Electrolysis II

In the second electrolysis a cylinder of thin zinc-plated sheet iron was used as cathode. From this cathode the deposited iron sheet could be removed without previously being heated. The electrolysis was carried out for 2 hours 30 minutes.

Average current 110.6 amp
Current density at cathode, 6.91 amp per sq. dm.
Average voltage 1.43 volts
Average temperature 94.5 deg. C.

The average speed of the cathode was 145 r.p.m., corresponding to a peripheral speed of 125 meters per minute.

Efficiency.—The sheet, in this case deposited on a zinc-plated cathode, could be removed without heating, but was very brittle and broke into a number of pieces. This was due to the high percentage of hydrogen. The pieces had a total weight of 274 grams, some pieces, however, being missing. In this case it is doubtful whether the sheet was perfectly dry. Furthermore, it was already somewhat oxidized at the time of weighing. After dipping a piece in boiling water it was a little less brittle. After heating in air it was no longer brittle but rather hard.

The sheet contained before heating a considerable quantity of hydrogen, namely, not less than 0.45 per cent, according to the analysis of the Material Testing Laboratories, of Stockholm, given below. In 27.4-gram iron sheet this amounts to 1.23 grams hydrogen and its deposition required 11.8 per cent of the coulombs consumed.

This percentage the inventor considers unusually high, but we have decided to figure with the values obtained in Electrolysis II, as well as Electrolysis I, which was performed in the same manner. In heating the sheet the hydrogen (1.23 grams) is removed and the weight of the tempered sheet is thus $27.4 - 1.2 = 26.2$ grams, corresponding to an efficiency of 94.5 per cent, since the theoretical weight of the deposit is 288.7 grams.

The ampere-hour balance sheet is therefore:

The iron sheet deposited corresponds to..... 94.5 per cent
Deposited hydrogen corresponds to..... 11.8 per cent

106.3 per cent

Oxidation and moisture on sheet and errors... -6.3 per cent

100.0 per cent

The current density in the Cowper-Coles method is approximately 6.8 amp. per sq. dm. at the cathode (it was in the two electrolyses 6.74 and 6.91 amp per sq. dm. respectively). The highest current density mentioned by Foerster is only 3 to 4 amp per sq. dm. and it seems, therefore, that Cowper-Coles has accomplished a considerable improvement in this respect. A high current density is desirable, even at the expense of a higher voltage, as it has a direct bearing on the time consumed, and thus increases the output of the plant.

Loss in Weight of Anodes.—In test II the total loss in weight at the three pig-iron anodes was ascertained in order to compare how this agreed with the ampere-hour consumption. After the anode slime had been removed the total loss was found to be 291.4 grams, while, under the assumption that the iron is dissolved as well as precipitated as bivalent, it is estimated that the iron taken off the anodes is equal to the amount deposited on the cathode, or 288.7 grams.

However, the anode slime removed weighed 20 grams and the weight of the iron deposited on the cathode was 272.8 grams, and as no increase in weight of the total percentage of iron in the solution had been noticed, it seems reasonable to expect that the difference between loss in weight of the anodes and the amount of iron deposited on the cathode would approximately equal the weight of the anode slime. This difference is $291.4 - 272.8 = 18.6$, which, indeed, nearly corresponds with the actual weight of the anode slime (20 grams).

That the anodes lose more than the weight of the iron deposited on the cathode is customary in electrolytic refining of impure metals and is in the present case due to the following causes:

It is to be expected that the carbon and silicon compounds and possibly sulphur and phosphorus compounds in the pig iron are affected not at all or only slightly by the current and remain as anode slime, which is gradually separated from the anode.

Further, small particles of iron are mechanically separated if the anodes are unevenly consumed.

If the weight of the anode slime is 20 grams, this would be 7 per cent of the iron consumed (219.4 grams). However, it is possible that this percentage of loss is too low.

On one hand it is possible that some slime has been separated from the anode during the operation, in which case the slime removed from the anode and weighed after the test was finished would be too low.

On the other hand, it is also possible, as stated above, that the value of deposited iron (272.8 grams) is somewhat high and consequently the difference between this value and the loss in weight of anodes is also too low.

In copper refining the anode slime is stated to be 4 per cent as a maximum, but the crude copper is considerably purer than the pig iron.

Since the composition of the anode slime, compared with that of the pig iron, is of considerable interest, the slime was analyzed by the Material Testing Laboratories of Stockholm, as well as the pig iron used in these experiments. The result was as follows:

	Pig Iron Used For Anodes	Anode Slime
Iron.....	93.11% (being the difference)	13.5%
Graphite.....	2.51, 2.81% total carbon	23.3, 23.8% total carbon
Combined carbon.....	0.30, 2.81% total carbon	0.5, 23.8% total carbon
Silicon (Si).....	2.30	33.9, corresponding to 15.9% Si
SiO ₂		
Manganese.....	0.43	1.5
Sulphur.....	0.10	1.78
Phosphorus.....	1.23	2.14
Copper.....	0.02	0.16
Chlorine, water, oxygen, etc.....		23.22 (difference)
	100%	100%

From this it is evident that in the anode slime, which still contains some mechanically separated iron, carbon, silicon and sulphur is greatly concentrated, while the phosphorus has been largely oxidized (phosphoric acid) and gone into the solution.

It is interesting to note that the copper is also concentrated in the anode slime and is not dissolved, quite in accord with observations in other electrolytic refining processes. Manganese is also somewhat concentrated, probably due to oxidation to peroxide.

Composition and Properties of the Deposited Sheet Iron

At the Material Testing Laboratories of the Royal Technical Institute, in Stockholm, the iron sheets produced in the tests have been analyzed as to chemical composition and tested as to rusting and mechanical and electrical properties. The analyzed material consisted of:

1. Iron sheet, 0.52 mm. thick, which had been heated and thereby rendered soft. It had been submitted by the inventor and is designated as El. 1 in the following.

2. Sheet produced in electrolysis 2, about 0.15 mm. thick, not previously tempered and consequently hard and very brittle, designated as El. 2 in the following.

A. CHEMICAL COMPOSITION

The results of the analysis are given below, together with the previously given analysis of the pig iron used for the anodes, which shows plainly the result of the refining.

	El. 1. 0.52 Mm. Tempered	El. 2. 0.15 Mm. Not Tempered	Pig Iron
Carbon.....	0.08%	0.06%	2.81%
Silicon.....	0.009		2.30
Manganese.....	0.05		0.43
Sulphur.....	0.02		0.10
Phosphorus.....	0.042		1.23
Chlorine.....	0.18 (=0.32% FeCl ₃)	0.49	
Hydrogen.....	0.021	0.45	
Hydrogen, after heating to 850° C.....	0.002		
Copper.....			0.02

A glance at these analyses shows at once that in regard to carbon, silicon, sulphur and phosphorus very good results are obtained, these elements being present in large quantities in the pig iron, while only small amounts are to be found in the electrolytically deposited sheet. The fact that even if steel anodes are used with a small percentage of carbon, and otherwise as pure as possible, their presence cannot totally be avoided is shown by older observations. The percentages in electrolytic iron are (according to Foerster) as follows:

C.	Si.	S.	P.
0.007-0.080%	0.003-0.01%	0.001%	0.004-0.02%

In regard to manganese it was shown previously by the analysis of the anode slime that it is somewhat concentrated. This indicates, as mentioned, that part of the manganese is oxidized at the anode and does not dissolve. Another part of

the manganese is probably dissolved as manganese chloride. That, nevertheless, such a small quantity of manganese is present in the cathodic iron sheet is probably due to the fact that the manganese being less "noble" than iron is not so readily deposited. It is, therefore, probable that it is concentrated in the solution in the same manner as the iron contained in crude copper is concentrated in copper refining. An older statement* that the manganese is not dissolved with the iron is not confirmed by the Cowper-Coles method.

As already mentioned, the percentage of hydrogen is remarkably high in the non-heated sheet. For information it may be mentioned that a percentage of 0.45 of hydrogen corresponds to not less than 394 units of hydrogen per unit of iron in volume, while the 0.021 and 0.002 per cent of hydrogen in the sheets, which had been heated, correspond to 18.4 and 1.75 units of hydrogen per unit of iron in volume respectively. That electrolytic iron contains a high percentage of hydrogen has long been known, earlier records, however, showing about 0.1 per cent (see Foerster, pp. 64-73). The high percentage in the iron sheet, produced by the Cowper-Coles method, is probably due to the high current density employed in this process.

Since by heating the sheet El. 1 at 850 deg. C. the percentage of hydrogen decreased from 0.021 to 0.002 per cent, the heating carried out by the inventor must have been done at a lower temperature or for a shorter time. As mentioned several times, the hydrogen makes the iron hard and very brittle and it must therefore be removed by heating.

The high percentage of chlorine is very remarkable and if it cannot be avoided it is very disadvantageous. It may be that the sheet was not well washed before heating or the sheet may have been a little porous and the pores retain some electrolyte, viz., iron chloride.

Therefore the percentage of iron chloride, FeCl_2 , was calculated from the percentage of chlorine in the above table. The fact that the very thin sheet, produced at our visit, which was not washed particularly well, gave a considerably higher percentage of iron chloride (0.88 per cent) than the other sheet (0.32 per cent) indicates that a thorough washing is very desirable. This might also decrease the percentage of sulphur and phosphorus.

As presence of iron chloride seems to promote the rusting of the sheet and also impair the mechanical properties of the iron, it is evidently of great importance to try to prevent the presence of iron chlorides. That there is a possibility of success in this respect has already been pointed out, and it is to be noted that in copper refining chloride has not been found in the cathode copper.

B. RUSTING

Comparative tests were made with sheet El. 1 and also a soft basic Martin sheet from Avesta (Sweden), 0.55 mm. thick, and with 0.1 per cent C., in the following designated as Av. Two polished pieces of each sheet were suspended in damp air; after three days the electrolytic sheet was considerably more defective than the Avesta sheet.

The explanation might be found in the presence of iron chloride in the electrolytic iron. This salt is deliquescent in damp air and can thus form a solution of the salt on the surface of the sheet, promoting electric local currents, which are believed to cause the rusting.

C. MECHANICAL PROPERTIES

We shall only mention some qualitative tests made with sheet El. 2 in order to show how the mechanical properties are improved by heating to a higher temperature and consequent removal of hydrogen.

The Testing Laboratory's bending test, after heating to various temperatures, was as follows:

A number of pieces of iron sheet were placed in an electric oven which was heated to increasing temperatures. At each 50 deg. rise in temperature one piece was taken out and this was continued until a piece could be bent double and straightened out again without cracking.

After heating to 450 deg. C. the sample broke at first attempt to bend. After heating to 500 deg. C. the sample could be bent to 90 deg., but cracks appeared when bent to 180 deg. After heating to 550 deg. C. the sample bent double without cracking. In straightening out cracks appeared. After heating to 600 deg. C. the sample bent double and straightened out without cracking.

According to these tests the sheet should be heated to 600 deg., at least if time is limited, for improving the sheet.

The effect of heating to higher temperatures (850 deg. C.) is shown in the following quantitative tests:

FIG. 2.—TEST PIECES

At these tests was used:

Electrolytic sheet, El. 1, (Fig. 2) the thickness of which was 0.52 mm and other dimensions 350 x 300 mm.

Martin sheet from Avesta, Av. (Fig. 2), the thickness of which was 0.55 mm and other dimensions 600 x 450.

Strips were taken from these sheets in two directions perpendicular to one another as shown by arrows 1 and 2 in Fig. 2.

Sheet El. 1 was not made in our presence and we cannot tell with certainty which direction on the deposited sheet cylinder corresponds to 1 and 2. However, it had streaks running parallel with arrow 1.

The samples were tested in their original condition and after heating to 850 deg. C. and cooling they were submitted to stress and bending tests.

The results are given in Table I:

TABLE I—STRESS TEST

Sample	Direction in Sheet	Physical Condition	DIMENSIONS			Tensile Strength, Kg. per Sq. Mm.	PLASTICITY IN PER CENT	
			Width, Mm.	Thickness, Mm.	Cross-Section, Sq. Mm.		Unit Length	100 Mm.
El. 1	1	Not heated	24.8	0.52	12.84	55.9	10.8	7.1
	2	Not heated	24.2	0.52	12.95	55.8	0.5	11.2
	1	Heated	24.5	0.52	12.58	58.2	15.3	11.8
	2	Heated	24.5	0.52	12.74	52.8	2.3	2.0
Av.	1	Not heated	24.7	0.55	13.59	41.0	11.3	8.6
	2	Not heated	24.1	0.55	13.50	33.1	16.0	15.2
	1	Heated	24.6	0.55	13.53	40.3	14.3	12.2
	2	Heated	24.8	0.55	13.64	36.3	13.3	11.3

Bending Test.—In this test samples 20 mm wide were bent over a bar with 2 mm radius, until the break occurred. The results are given in Table II:

TABLE II—BENDING TESTS

Sample	Direction in Sheet	Physical Condition	Number of Bends to 90° and Reversals, Average of 3 Tests
El. 1	1	Not heated	3
	2	Not heated	3
	1	Heated	11
	2	Heated	10
Av.	1	Not heated	12
	2	Not heated	28
	1	Heated	18
	2	Heated	20

The results of further tests are given in Table III

D. ELECTRIC PROPERTIES

The electrolytic sheet (El. I) tempered at 850 deg. C. had at 16 deg. C. a resistance of 0.116 ohm per 1 m. length and 1 sq. mm cross section or 11.6 microhm per cm². With Benedick's formula* the specific resistance of the sheet in non-heated condition (percentage of hydrogen = 0.002 per cent) is calculated to be 11.4 microhms per cm² at "ordinary temperature," which corresponds very nearly with the direct measurements.

In the calculations the chlorine is not considered as it probably exists as iron chloride. It was our intention to investigate also the magnetic properties but shortage of material prevented us from doing so.

It is to be expected that, due to its pure state, the sheet will show very small hysteresis loss. For purposes where this is desirable high electric resistance is usually also wanted, which the electrolytic iron does not possess.

But the electrolytic sheet iron can be made so exceedingly thin (probably about 0.05 mm) that the hysteresis and eddy currents can be brought down to a reasonable amount.

It seems therefore possible that the electrolytic iron can favorably compete with the nickel and aluminium steel which are produced at a thickness of about 0.35 mm by means of rolling for purposes where low hysteresis loss and high electric resistivity is desirable.

Another desirable property of the electrolytic iron is its high permeability. It is stated that an 1/2-hp motor, after having been equipped with poles of electrolytic iron, made according to F. Fischer's method, delivered 1 1/4 hp. (See Svensk Kemisk Tidskrift referred to above.)

Some Factors Which Influence the Economical Result of This Process

As stated above the percentage of carbon can not be regulated, but it can always be assumed that the product obtained by this process contains only a small percentage of carbon, viz., it is a soft sheet or tube. If sheet iron of great length or width is wanted the cylinder must be of very large dimensions. On the other hand tubes, of which we have seen samples, can be made of greatly varying diameter and length and we wish to call attention to the fact that copper tubes have been made successfully by electrolytic processes in a similar manner.

In regard to thickness of material it seems that the inventor has not as yet produced tubes thicker than 2 mm. He did not, however, anticipate any other difficulties in the production of heavier material than possibly that of the weight.

On the other hand in rolling the thin sheet is the final and most expensive product while in the electrolytic process it is the one most quickly and easily produced. The prospects of the process would, therefore, probably lie in the production of thin sheets and tubes of soft steel.

One defect in the process is the method of removing the sheet and heating. In the description of Electrolysis I it was mentioned that the iron was deposited on a copper-plated cylinder, K, which was taken off the cylinder, C, and heated, after which the deposited sheet iron could be taken off and was

soft. This method will undoubtedly be troublesome in making large sheets, as the cylinder, K, would have to be of very large size. In making tubes the method is simpler.

More serious will be the condition of the cylinder, K, when in constant use, which will probably require renewed copper plating. To remove the sheet without previous heating as was done in Electrolysis II is impossible in commercial practice, as the sheet will break into pieces. The inventor made several suggestions for remedying this defect.

Consumption of Pig Iron

As stated above, the consumption of pig iron is larger than the weight of the deposited iron. The weight of the anode slime is according to our observations about 7 per cent of the weight of the consumed pig iron. This estimate, however, may be too low. We shall, therefore, assume a somewhat larger loss—say 1.1 ton of pig iron is required for producing 1 ton sheet iron—without stating, however, that this figure is on the safe side. This 1.1 ton of pig iron should then represent the amount of iron dissolved and deposited plus the anode slime per ton of product.

In this connection it should be pointed out that, disregarding the anode slime, the anodes cannot be completely utilized: when only a portion is left the voltage increases and it must be replaced, while it also happens that an anode is eaten through and a large portion is entirely separated.

The portions remaining can, of course, be collected and recast, which will slightly add to the cost of production. The same applies to the trimmings of the sheet iron. How long the anodes can be used before replacing can only be decided from experience extending over a long time. As a matter of information it may be mentioned that 90 per cent of the anodes used in copper refining can be utilized before recasting.

Energy Consumption

A. FOR ELECTROLYSIS

In the two electrolyses performed in our presence the mean emf. was 1.34 and 1.43 volt respectively or an average of 1.385 volt per cell. This voltage was measured between anode and cathode and to this should be added losses in conductors. This voltage could probably be decreased to some extent by covering the whole inside of tank, B, with anodes. It may, therefore, be safe to figure on a tension of 1.5 volt per electrolyzer.

The ampere-hour efficiency we assumed to be 85 per cent, figuring on 12 per cent loss in precipitation of hydrogen and 3 per cent mechanical losses in removing and trimming the sheets.

For the horsepower year we assume the year to be 350 × 24 = 8,400 hours as usual in electrochemical work.

Further as 1 amp-hour at 100 per cent efficiency will deposit 1.045 grain iron from a ferrous salt solution and as 1 hp equals 0.736 kw we find that one electric hp-year at the electrolyzer should produce 3.7 tons (metric tons of 2,204 lbs. each) of iron sheets or tubes. Or for the production of 1 ton of iron sheet or tube 0.27 electric hp-year is required.

B. FOR MOTOR SERVICE

Electrical energy is also required for the operation of the motors for rotating the cathode, the operation of the pumps, the mechanical treatment of the product and for lighting. Exact information as to the energy required for these purposes cannot be obtained at present, but it can hardly be of great importance compared with the energy requirements for the electrolysis, probably amounting to 1/5 of the latter.

Cost of Labor.—The inventor states, without furnishing further data, that about 50 hours of manual labor is required per ton of products. In this connection it is to be noted that electrolytic processes are practically automatic and require very little attention.

Heating and Maintenance of the Electrolyte.—We did not receive from the inventor any information from which satisfactory estimates can be made as to such cost. The analyses given herein show no change in the composition of the solu-

* Benedick, *Recherches physiques et physico-chimiques sur l'acier au carbone*, Upsala 1904, p. 113.

tion due to the electrolysis, with the exception that the amount of slime had increased, which may be due to the difficulty in obtaining uniform samples. From the short investigation we made of the process it is too precarious to draw any conclusions in regard to the life of the electrolyte.

The cost of finishing the author has estimated at about \$1.50 per ton.

Depreciation.—According to figures submitted by the inventor the first cost—exclusive of power station and iron supply—amounts to approximately \$100 per ton of iron sheet produced per year, buildings amounting to about \$1,600. Allowing 5 per cent for depreciation of buildings and 10 per cent for other items the annual amortization amounts to $\$0.80 + \$8.40 = \$9.20$. The inventor figures only with an amortization at \$1.60 which seems to be too low. This is mentioned only to show that the cost of amortization is a rather large factor, principally due to the high cost of the electrolyzer.

Interest on Investment in Stored Pig Iron.—Electrolytic refining processes operate rather slowly. In Electrolysis II a 6-mm sheet was deposited in 1 hour with the current density used by Cowper-Coles and to produce a 10 mm sheet would require about 7 days of 24 hours. In connection with such processes consideration must, therefore, be given to the interest on stored raw material.

In electrolytic copper refining the interest on the amount invested in raw material is of very great importance and this has been the primary reason for endeavoring to increase the speed of operation as much as possible, that is, operate with highest possible current density. In the Cowper-Coles process the current density is higher—since in copper refining it hardly exceeds 4 amp. per sq. diameter—and beside this the raw material is of comparatively small value, and, therefore, the interest on the amount invested in raw material in iron refining is of no consequence. The inventor has estimated that with an annual production of 5000 tons, a permanent supply of 1000 tons would be sufficient, which is probably ample, judging from the experiences of copper refining. If the value of 1000 tons of pig iron is \$16,000—the interest at 6 per cent would be \$970—or about 19 cents per ton of production.

The Application of the Method for Reduction of Iron Ore

In his lecture before the Iron and Steel Institute Mr. Cowper-Coles also mentioned the application of his method for producing iron sheet and tubes of high quality from iron ore. The inventor has not, however, as yet developed his method for this purpose. On account of the great importance of this matter we wish to add a few words on the subject.

The method which would first suggest itself for realizing the purpose would be to dissolve the ore by acids and extract the iron electrolytically.

In regard to the solubility of iron ores we wish to point out that siderite and bog ore dissolve relatively easily in acids while magnetite and hematite require heating with concentrated sulphuric acid or concentrated hydrochloric acid.

For dissolving 1 ton hematite about 2.76 tons of pure H_2SO_4 are required. On account of the hydrolysis of the iron salts more acid is required than the equivalent weight, for which allowance has been made and 5 per cent has been added; 2.76 tons pure sulphuric acid corresponds to 4.4 ton chamber acid with 62.0 per cent H_2SO_4 . The price of chamber acid is about \$5.50 per ton, possibly less. The cost of only the acid will thus be about \$24 per ton. For magnetite the cost is 8/10 of this or about \$21.50.

With hydrochloric acid the cost is considerably higher. It is, therefore, evident that this application of the process will be commercially possible only if the acid can be regenerated, which is a possibility. In this case carbon or some other inert substance should be used, as anode.

Furthermore, for the regeneration of the acid a diaphragm would have to be used to separate anode and cathode. Under this circumstance and as long as the cathode consists of a rotating cylinder, the apparatus will be rather complicated.

If hydrochloric acid is used the regeneration could be ac-

complished by passing the chlorine, which is developed at the anode from the iron chloride solution, together with steam over incandescing coke.

In using hydrochloric acid there would be added, however, a considerable expense for evaporating the water absorbed in the circulating process. This might also occur in connection with sulphuric acid.

On account of the necessity of using insoluble anodes instead of soluble pig-iron anodes the voltage would be higher. From observations in other electrochemical processes it may be estimated that not less than 5 volts would be required. Assuming an efficiency of 85 per cent as before hematite ore would yield per hp-year 0.73 ton or 1 ton iron would be deposited by 1.37 hp-year. Magnetite would yield 0.82 ton per hp-year and 1 ton of iron would be deposited at the expense of 1.22 hp-year.

In this case, soft steel, practically free from carbon, would be produced, unless some new startling innovations are made, and the amortization of the expensive plant would be quite heavy.

At the present state of developments we shall not venture to express any opinion as to the future possibilities of the process with respect to its application to the direct reduction from iron ores.

Stockholm, Sweden.

The Outcome of the Carborundum Patent Suit

The patent law suit of many years between the Electric Smelting & Aluminum Company and the Carborundum Company has now reached what would appear to be its final stage, by a decision rendered on March 15 in the United States Circuit Court of Appeals for the Third Circuit.

The case was tried before Circuit Judge Gray and District Judges Bradford and Young. The decision is written by Judge Bradford. A dissenting opinion was handed down by Judge Young.

From the decision written by Judge Bradford we quote the following:

"These appeals have been taken from a final decree of the Circuit Court of the United States for the Western District of Pennsylvania made Feb. 21, 1911, confirming the report of a master on an accounting of profits for patent infringement ordered by that court, in this case Dec. 7, 1900. The original suit for infringement was brought by the Electric Smelting & Aluminum Company, hereinafter called the complainant, against the Carborundum Company, hereinafter called the defendant, for infringement of three United States patents, No. 319,795 for 'Processes for Smelting Ores by the Electric Current,' No. 319,945 for 'Electric Smelting Furnaces' and No. 335,058 for 'Electric Furnaces and Method of Operating the Same.'

"The two first-named patents were issued to Eugene H. Cowles and Alfred H. Cowles June 9, 1885, and the last-named patent to Alfred H. Cowles Jan. 20, 1886, and all of these patents were assigned to the complainant. At the final hearing in the Circuit Court the charge of infringement of Patent No. 335,058 was abandoned, and that court held that neither of the other two patents had been infringed.

"On appeal to this court the decree of the Circuit Court was in May, 1900, affirmed as to Patent No. 319,945, but reversed as to Patent No. 319,795; it being held by this court that claims 1, 2 and 4 of the last-named patent had been infringed by the defendant, and the case was referred by the court below pursuant to the decree of this court to a master for an accounting of profits derived by the defendant from the infringement.

"The defendant thereafter and while the case was in the hands of the master adopted, Jan. 1, 1901, what it claimed to be a different and non-infringing process, and in the language of its counsel, 'did it almost on the instant,' and claimed that it was not bound to account for any profits derived from its manufacture and sale of carborundum after Dec. 31, 1900, as at that time it discontinued using the process held to have been infringed. This claim the complainant denies, contending that

the alleged new process was a clear infringement of Patent No. 319,795.

"The master decided in December, 1906, that the alleged new process was not an infringement of that patent, limited the accounting to Dec. 31, 1900, and made an award of \$22,411.62 in favor of the complainant, all of which was confirmed by the court below.

"Before taking up the question of the sufficiency of the sum awarded to the complainant as profits during the accounting period up to and including Dec. 31, 1900, we shall briefly consider whether the defendant was not thereafter guilty of infringement of the complainant's process for which it should have been compelled to account.

"We think the court below was in error in holding that the process employed by the defendant from and including Jan. 1, 1901, to June 9, 1902, the date of the expiration of Patent No. 319,795, was not an infringement of that patent, and that the complainant was not entitled to profits gained by the defendant from the use of that process during that period. This court in and by its decree in 1900 reversed the decree of the court below and decided that claims 1, 2 and 4 of that patent were valid and had been infringed by the defendant. These claims are as follows:

"1. The method of generating heat for metallurgical operations herein described, which consists in passing an electric current through a body of broken or pulverized resistance material that forms a continuous part of the electric circuit, the ore to be treated by the process being brought into contact with the broken or pulverized resistance material, whereby the heat is generated by the resistance of the broken or pulverized body throughout its mass, and the operation can be performed solely by means of electrical energy.

"2. The method of smelting or reducing ores or metalliferous compounds herein described, which consists in subjecting the ore in the presence of carbon to the action of heat generated by passing an electric current through a body of broken or pulverized resistance material that forms a continuous part of the electric circuit, the ore being in contact with the broken or pulverized resistance material, whereby the ore is reduced by the combined action of the carbon and of the heat generated solely by the resistance of the broken or pulverized body throughout its mass.

"3. The method of smelting or reducing ores or metalliferous compounds herein described, which consists in subjecting the ore in the presence of a reducing agent to the action of heat generated by passing an electric current through a body of broken or pulverized resistance material that forms a continuous part of the electric circuit, the ore being in contact with the broken or pulverized resistance material, whereby the ore is reduced by the combined action of the reducing agent and of the heat generated solely by the resistance of the broken or pulverized body throughout its mass.

"The claims of the patent should be liberally construed for reasons heretofore given by this court in this suit, as follows: 'On careful examination we have failed to find in any patent, publication or other matter alleged as an anticipation or as showing the prior art, a practical process for metallurgical or analogous operations involving the use of a discrete body of conductive but resistant material rendered incandescent by the passage of an electric current and mixed or otherwise in contact with the material to be treated. This is the broad underlying idea of the process patent in suit, and is well covered by its claims. The Messrs. Cowles were the first to invent and use this process and the patent must be sustained. It is a meritorious one and its claims are entitled to considerable liberality of construction.'

"This court has declared in this case in relation to the core used by the defendant 'The use of the central core of resistance material is within the process of the appellant under claims 1, 2 and 4. These claims require merely contact in contradistinction to a mixture between the resistance material and the material to be treated, and it is immaterial whether, under those claims the body of resistance material assumes the

form of a central core or any other shape, so long as it is in contact with the material to be treated, is discrete, granular or pulverized in its composition, is rendered incandescent through the passage of electric current through its mass or over its area, and thereby affords the heat to effect the desired end.'

"And further: 'If claims 1, 2 and 4 are broad enough to include actual contact of any kind between the two materials, the resistance material forming part of the electric circuit may be in contact with the material to be treated, whether in the form of a core or several cores, or of strata, or in any other form, to secure the most effective operation of the process under varying conditions involving the nature of the material to be treated, amount of the charge, etc.'

"And in the description of the patent it is stated: 'The scope of this invention is not limited by the degree of granulation, as that may vary with the conditions of the case, and with a large furnace and a powerful current the size of the carbon particles may pass beyond what is ordinarily understood by the term granular and be in fact pieces of carbon of considerable size.'

"The defendant in its alleged new process employed a block core consisting of a number of blocks of electric light carbon, each 32 in. long and 4 by 4 in. in thickness. They are arranged in 'zig-zag' fashion and the ends of each two blocks forming a V rest upon a carbon block from 12 to 14 in. long and 4 by 4 in. in thickness, called a connector block. A large quantity of fine granular or pulverized carbon, or graphite, is disposed between the carbon blocks and around their ends on the connector blocks, and also a large quantity of granular or crushed coke is disposed at each end of the furnace to convey the electric current to and from the electrodes to the black core, that core being in electrical connection with the electrodes at each end of the furnace.

"Notwithstanding the furnace in the arrangement of the resistance material we are satisfied on the evidence that the alleged new process practised by the defendant since Dec. 31, 1900, is the process, the use of which by the defendant this court held to infringe claims 1, 2 and 4 of Patent No. 319,795; the mere mechanical difference in the form and arrangement of the core not serving to affect or change the nature of the process or to shield the defendant from responsibility. The defendant must, therefore, be required to account to the complainant for all profits gained by the former from its manufacture of carborundum under the alleged new process, and its sale, from and including Jan. 1, 1901, to June 9, 1902."

The opinion then takes up in detail the manner in which the sum awarded to the complainant had been arrived at by the master. The total net profits during the accounting period had been \$104,525.74.

"The master deducted from the \$104,525.74, representing total profits, 49.55 per cent thereof, or \$50,792.51, for 'profit properly belonging to the invention of the defendant of the product, carborundum itself,' and 'the profit belonging to the invention of defendants of the bonding material, that under the evidence made the great bulk of the sales of carborundum possible by the defendant company.' After deducting from the total profits the above sum of \$50,792.51, the master apportioned to the complainant, but subject to further deduction, the remaining 50.45 per cent, amounting to \$52,733.23.

"This apportionment was arrived at by ascertaining that the cost of the entire output of the defendant's business during the period of infringement was \$469,665, and that the cost of making carborundum, including its cleaning, crushing, grading, and preparation for sale, was \$236,944.53, or 50.45 per cent of the total cost of the defendant's output, and by assuming that 'each dollar of expenditure by the defendant earned an equal amount of profit.'

"He then proceeded to deduct from the above sum of \$52,733.23 15 per cent thereof as representing the difference between the 'whole cost of carborundum production' and the 'furnace cost,' being \$7,009.99, leaving a balance, subject to further reduction, of \$44,823.24 as 'the part of the profits to which the use of complainant's process in the production of

carborundum contributed, after consideration of the foregoing elements as entering into that profit."

"The master next proceeded to deduct one-half of the above sum of \$44,823.24 as the amount of the supposed contribution to the defendant's profits through its ownership of an Acheson patent and its re-issue for carborundum granted subsequent to the issuance of Patent No. 319,795 in suit, and awarded to the complainant the remaining half, namely, \$22,411.62 as the total amount it was entitled to receive under the accounting ordered by the court below pursuant to the decree of this court, together with the costs of accounting. . . .

"The complainant contends that in addition to such sum as may be decreed to it for profits made by the defendant from its infringement of Patent No. 319,795 during the period from Dec. 31, 1900, to June 9, 1902, the complainant is entitled to recover from the defendant the above sum of \$104,525.74 without deduction. This contention is based upon two grounds: first, that whatever profit there is or has been in the defendant's business has been derived solely through its infringement of the complainant's process, and, secondly, that, if it be assumed that the first ground is untenable, there has been such negligence on the part of the defendant in failing to keep accounts showing the amount of profit derived by it from the infringement that the complainant is entitled to recover the total profits of the defendant's business.

"The first of these grounds we think is well taken. It clearly appears from the evidence that the business of the defendant is based upon and practically confined to the manufacture and sale of carborundum in one form or another. As stated by the court below in its opinion (189 Fed. 710) as to a proper form of decree to be made under the decision of this court on final hearing (102 Fed. 618): 'The respondent has a large plant built and adapted for the manufacture of carborundum. The machinery and apparatus were likewise built for that special work. It is respondent's sole business, and in that article and its application they have built up a large trade and extensive use.'

"The making of wheels, cloth, paper, etc., covered in whole or in part with carborundum is wholly subsidiary or incidental to its advantageous sale. Admittedly it would be impossible for the defendant without its wrongful use of complainant's process to carry on its carborundum operations. Not only could it earn no profits, but its business would cease to exist; for no other process for the manufacture of carborundum than that of the complainant has been disclosed.

"Much has been said on the subject of the Acheson process and product patents No. 492,707, of Feb. 28, 1893, and re-issue No. 11,473, of Feb. 26, 1895, for 'Improvements in the Production of Artificial Crystalline Carbonaceous Materials.' In the description in both of these patents Acheson states: 'My invention consists in the various processes and products of said processes substantially as hereinafter more particularly set forth. . . . I do not limit myself to any of the particulars set forth, as I intend to cover and claim broadly the new crystalline carbonaceous materials whether produced by the particular processes or methods set forth, or by any substantially equivalent methods, and for all purposes to which it may be applied.'

"And his claims were as broad as his statement of invention. It is contended in substance by the defendant that the patent in suit, while covering the process of manufacturing carborundum, does not cover the article itself; that Acheson was the original inventor and discoverer of the article; that the defendant, as his assignee, has a monopoly in that article how ever or wherever or by whomsoever produced in this country; and, therefore, that the carborundum sold by the defendant in the conduct of its business, although manufactured in defiance of the patent in suit, must be treated as a contribution by the defendant towards profits realized and be considered on the accounting in question.

"A valid process patent, though for a process only, confers on that patentee a right to exclude all others from using such process for the attainment of its object. Others may secure

the desired result, if they can, by the employment of a different process, if open to them, but they cannot without leave or license of the patent owner use the patented process with impunity. And on an accounting for profits, and not for damages, in a case of infringement, where profits to the infringer are impossible save through his infringement, he must be treated as a trustee *ex maleficio* and can withhold none of his gains from the patentee. The fact that in such a case the patent is not for the product, but only for the process, is wholly immaterial; for the infringer will not be permitted by a court of equity to take advantage of his own wrong, but will be held accountable as a trustee of the profits.

"It is well settled that, in the case of mechanical inventions, where the infringed patent covers a mere improvement upon mechanism before known and open to the defendant to use, the complainant can recover only the excess of such profits as have been realized through the use of the improvement over what the defendant might have made by the use of such mechanism without such improvement. But it is equally well settled that where the entire commercial value of the mechanism arises from the patented improvement the owner of the patent will be entitled to recover from the infringer the total profits derived from the manufacture, use or sale of such mechanism. . . .

"Nor is the application of the rule affected in a case where profits, and not damages, are to be accounted for by the fact that the owner of the patent has not used the mechanism containing such patented improvement. *Crosby Valve Company vs. Safety Valve Company*, supra. The principle of the foregoing cases, involving the consideration of mechanical inventions, is not without much weight in the determination of the question of profits in the case before us. We think it applies *a fortiori* here, as it was only through the infringement of the complainant's process that profits were made, or indeed, were possible. For, as above stated, no other process than that of the complainant is disclosed under which carborundum can be manufactured.

"Further, the holder of a valid process patent has a right not only to manufacture under the patented process, but to use and sell the product, unless that product be the subject of a valid patent monopoly in favor of another person. The defendant contends that under and by virtue of the Acheson patent it has a monopoly in the product carborundum. If it had such a monopoly it would seem to follow that, save in so far as equitable considerations might produce a different result, it would have the exclusive right to use and sell carborundum whether wrongfully manufactured by itself or rightfully manufactured by the complainant; and in the latter case under the process patent upheld by this court as valid and meritorious while the complainant would have the exclusive right to manufacture carborundum under its process, it would be powerless to use or sell a pound of such manufactured product. It is not perceptible that under such circumstances the process patent would have any value.

"A clear case should be made to justify the court in treating the defendant's product patent as operative or enforceable against the complainant and thus practically nullify the process patent so far as it covers the manufacture of carborundum. Acheson did not discover, invent or have any idea of carborundum until long after the patent in suit was granted.

"On final hearing not only his patents, but much evidence touching his connection with the product, were before this court when it was said: 'We have no doubt on the evidence that carborundum can be and has been produced under the process covered by any of the claims of the process patent in suit, although not so efficiently or profitable under the method of claim 3. So long ago as 1884 the Messrs. Cowles produced it under their process with and without the use of a prepared or pre-formed central core of resistance material. It is true they did not manufacture it for commercial purposes and, failing to appreciate its importance, though aware of its abrasive qualities, applied their process to other branches of metallurgy.'

"And, further. 'The Messrs. Cowles were the first to invent and use this process and the patent must be sustained.'

"It appears from the evidence that, although carborundum was not manufactured on a commercial scale before the Acheson product patent was obtained, specimens of carborundum made by the Messrs. Cowles and the Cowles Electric Smelting & Aluminum Company, the assignor of the complainant, were placed on exhibition in different parts of the country and much notoriety was given through lectures and printed publications to the incandescent feature of the patent in suit. The Messrs. Cowles, it is true, failed to appreciate the importance of the product, as above stated, and did not know it by the name of carborundum—for it had yet not been so christened—and were not familiar with its composition, but they were aware of its highly abrasive qualities.

"There is no evidence that the Messrs. Cowles or their successors in the title to the process patent in suit ever intended to abandon that process so far as the manufacture of carborundum is concerned. The fact that they exhibited from time to time and in different places specimens of what is now known as carborundum strongly indicates an intention on their part not to exclude that product from the operation of the process patent. This court has decided that the process patent in suit is valid, meritorious, and entitled to considerable liberality of construction.

"This case presents some unusual features. Under the process Patent No. 319,795 the Messrs. Cowles and the Cowles Electric Smelting & Aluminum Company had a right, fully sustained by this court to manufacture carborundum, and they also had a right—certainly until the Acheson patent was obtained—though not necessarily an exclusive right to use and sell any carborundum made by them. In fact, they did make carborundum under the patented process, though not on a commercial scale. As before stated, there is no evidence that they or the complainant ever abandoned the right to apply the patented process to the manufacture of that article. The Acheson patent and its re-issue, which were obtained a number of years after the patent in suit, claimed not only carborundum but also a process for the production of that article. This court has decided that the defendant in using the process claimed by Acheson used the process of the patent in suit and was guilty of infringement. It does not appear that there was any other process under which carborundum could be produced.

"If the Acheson patent so far as it claims the product in contradistinction to the process should be held to confer upon the defendant the exclusive right to use and sell carborundum, then, as before indicated, the complainant's process patent was held absolutely at the mercy of the defendant; for the bare right to manufacture without a right to use or sell what is manufactured is valueless.

"While it has repeatedly been stated that a patent may be obtained for a process in contradistinction to its product, or for a product in contradistinction to the process under which it is created, we can recall no case in which it has been held that after a valid process patent has been granted and applied to the production of an article, though not on a commercial scale, and there has been no abandonment by the patent owner of the right to apply the process to the production of the article on such scale, and such article can be produced only under that process, another person can obtain a patent conferring upon him an exclusive right, as against the holder of the process patent, to the use and sale of the article so produced and thereby wholly destroy the value to him of the process patent so far as it may be applied to the production of such article.

"If such a product patent can validly be obtained it would be necessary in order to avoid gross injustice to the owner of the process patent that all profits rendered possible only through the infringement of the process patent should be awarded to the latter, and to that end the infringer should be treated as a trustee *ex maleficio* of the profits.

Patents are not granted to serve as instrumentalities for the perpetration of fraud or the doing of injustice. They are

property, but, like other property, must be used legitimately. We perceive no reason why the aphorism *sic utere tuo ut alienum non laedas* is not applicable to the use of a patent as well as of other property. To permit one who holds a subsequent product patent to infringe a prior process patent, without which process the product could not be created, and then shield himself in whole or in part from liability for his wrongdoing by setting up his product patent, would not accord with the principles usually obtaining in courts of equity. Under such circumstances the least that equity demands is that the wrongdoer be compelled to disgorge his ill-gotten gains.

"But it is not necessary that we should in this case express an opinion upon the validity or invalidity of the Acheson product patent or its reissue. For whether the defendant did or did not hold a valid patent for carborundum as a product is, as has appeared, immaterial to the decision of the question of profits; for profits having been rendered possible only through the infringement of Patent No. 319,795 the whole amount under the doctrines of the authorities above cited must be awarded to the complainant.

"The decree of the court below must be reversed, with costs to the Electric Smelting & Aluminum Company in this court and the court below, and this case be remanded to the court below with directions that the Electric Smelting & Aluminum Company recover from the Carborundum Company upon a further accounting in the court below the total profits realized by the latter from its manufacture of carborundum and its sale from and including Jan. 1, 1901, to June 9, 1902, together with legal interest thereon from the proper date; and further, that the Electric Smelting & Aluminum Company recover from the Carborundum Company the above-mentioned sum of \$88,743.30, together with legal interest thereon from Feb. 21, 1911; and that such further proceedings be had in the court below as shall dispose of this case in accordance with the views herein expressed. A decree may be prepared and submitted."

Judge Young, in his dissenting opinion "concurs in the foregoing opinion so far as it finds the Carborundum Company guilty of infringement of the process patent in suit during the period from and including Jan. 1, 1901, to June 2, 1902; but dissents from such opinion so far as it holds that the profits realized by the Carborundum Company from its infringement of said patent, together with interest and costs, should not be apportioned between the parties in accordance with the decree of the court below, but awards the total profits, interest thereon, and costs to the Electric Smelting & Aluminum Company."

Barium sulphate precipitated in the determination of barium is likely to be contaminated with occluded alkali salts. Owing to the fine state of subdivision of the precipitate it is difficult to wash these salts into the filtrate. Gooch and Hill, (*Amer. Journ. Sci.*, March, 1913), have found that the precipitate may be made coarsely crystalline and easily washed by dissolving the sulphate in sulphuric acid and then evaporating to dryness by directing the flame of a blast lamp directly onto the solution. In order to avoid loss by spattering, a platinum gauze cone is inverted in the mouth of the crucible. The operation is more rapid than evaporation by a Hempel burner, the time required being about 15 minutes, as compared with from one-half hour to several hours by other methods.

The second annual report of the Director of the U. S. Bureau of Mines, for the year ended June 30, 1912, has just been issued. Among the tangible benefits resulting from the Bureau's work are, improvements in mine safety and in mining conditions, laws and regulations for mine safety, and fuel investigations. The general adoption of permissible explosives, having a short and relatively cool flame, has resulted in reducing accidents. A great deal of money has been saved to the government by specifying grades and quality in fuel purchases. Among the needs of the Bureau are suitable buildings, grounds and equipment for carrying on experimental work at Pittsburgh, extension of mine-rescue and first-aid work, extension of investigations on mine accidents, extension of investigations on mineral waste and metal mining industries.

"Exothermic Steel."

Discussion Before the Pittsburgh Section of the American Electrochemical Society

The third meeting of the Pittsburgh section of the American Electrochemical Society was held at the German Club on the evening of February 19, at the conclusion of an informal dinner. The chairman of the section, Mr. C. G. Schleudergberg, presided.

In the preceding meeting Mr. Walter O. Amsler had spoken on the "exothermic steel" process (this journal, vol. X, p. 559, September, 1912) and the present meeting was devoted to two reports on experiments made with this process by Mr. W. W. Clark, chief chemist of the American Vanadium Company, and Mr. Philo Kemery, metallurgical engineer of the Crescent Works of the Crucible Steel Company of America.

Mr. Clark first presented his report as follows:

Report by Mr. W. W. Clark

At our last meeting Mr. Amsler gave us a little talk on his so-called new process of making steel and its product "exothermic steel." The paper had previously been published in *METALLURGICAL AND CHEMICAL ENGINEERING* (vol. X, p. 559), where it received considerable criticism from the different iron and steel metallurgists throughout the country (vol. X, pp. 712, 713, 774, 775, 776).

To give a short synopsis of Mr. Amsler's talk, he takes a mixture of iron ore, feldspar, lime and bauxite, which he heats to 1800 deg. Fahr., or about 1000 deg. C. in a graphite crucible. At this temperature a violent reaction is supposed to take place, with sufficient evolution of heat to raise the temperature of the entire mass above the melting point of the steel, while all the iron oxide is reduced to the metal.

He first claimed that the feldspar and bauxite did the trick, and in his article had a composition formula for feldspar, which, if it were possible, would reduce some iron. He also had the reaction which took place between the iron oxide and the feldspar, showing how the iron was reduced.

He admitted that he did not know anything about this formula, as he was not a scientific man at all, but had just assumed the formula to suit the case, but said that if it were that way it would reduce some iron, but we know from analysis and from all the known laws of chemistry and metallurgy, that it is impossible for feldspar to take up oxygen. He later admitted that maybe feldspar did not do the work, and that carbon entered into the reaction, but still insisted that he was making steel that way, and would be glad to show one or all of us, how it was done.

He also stated that the steel had been in use for some time at the Bureau of Mines in the shape of cannon for the testing of the explosive power of the different powders. Upon investigation of this steel, the Bureau of Mines did not know anything about exothermic steel, but said that they had bought steel from Mr. Fogler, who had a shop in the west end of Pittsburgh, and that it was very good steel, but they were unable to say how it was made. The cannon came to them ready to use.

Taking Mr. Amsler at his word, I offered him the use of our laboratories to test out his process in the presence of two or three of the eminent steel metallurgists of the Pittsburgh district, and although since that time, I have telephoned and written Mr. Amsler, I have been unable to get him to come.

A number of experiments were made, following Mr. Amsler's directions given at our last meeting with negative results, and also some following new directions sent by Mr. Amsler in a letter to me which reads as follows:

"I am at the present time very busy with contract work which must be gotten out at a certain date, but if I can possibly arrange it I will come out to your laboratory some time next week. In making your experiments in a small crucible, try using 6 or 8 oz. of ore, $\frac{1}{2}$ oz. of bauxite, 1 oz. of feldspar and $\frac{1}{2}$ oz. of lime. In heating this charge be sure to use a reducing flame, or cover in such a manner that the oxygen

from your fire cannot enter the crucible. This is essential as otherwise the oxygen absorbing properties of the flux will be satisfied with the free oxygen, rather than that which is in combination with the iron in the ore. I believe under these conditions you will be able to show practically all of the iron in the ore in a metallic state. (Signed) Walter O. Amsler."

A No. 4 Dixon graphite crucible was used in each case where carbon was present, while an alundum crucible was used for the experiments in the absence of carbon. A platinum-platinum rhodium couple and a Siemens-Halske galvanometer were used to record the temperatures. When carbon was present carbon fire ends outside quartz were used, while in the experiments without carbon, the couple was protected by magnesite. The crucibles were placed inside a larger crucible, the space between packed with pulverized coke, and tight covers placed on both. A small hole was bored through both of the covers for the insertion of the thermo-couple.

Experiment 1.—Mix: 6 oz. pure iron oxide, $\frac{1}{2}$ oz. bauxite, 1 oz. feldspar and $\frac{1}{2}$ oz. lime.

The material was carefully weighed and mixed, and then ground to 80 mesh. The crucible was placed in a larger crucible, packed with coke, charged with the above mix, the covers adjusted, and the whole transferred to the furnace which had previously been heated to 1000 deg. C. The mix was held at this temperature for 3 hours. The melt was pasty and after cooling showed small globules of iron scattered throughout the mass with the majority around the edge, where it had come in contact with the carbon of the crucible. The whole melt was weighed and showed by analysis that about 7.5 per cent of the iron had been reduced. Temperature variation 106 deg. C.

Experiment 2.—Mix: Same as in experiment 1.

Brought to 1000 deg. for 1 hour and then raised to 1250 deg. for 2½ hours. The melt was fluid and a small amount of iron had been reduced. This by analysis showed 13 per cent of the iron reduced. Temperature variation at 1000 deg.—64 deg. C. and at 1250 deg.—94 deg. C.

Experiment 3.—Mix: Same as in experiment 1. Brought to 1450 deg. for 3 hours. Melt was very active and poured clean. The iron had been melted and settled to the bottom. This by analysis showed 28 per cent of the iron reduced. Temperature variation 103 deg. C.

Experiment 4.—Mix: Same as in experiment 1. Melted in an alundum crucible. Held at 1250 deg. for 3 hours. The melt was fluid and after cooling showed fine homogeneous structure. By analysis this showed 0.20 per cent of the total iron reduced. Temperature variation 47 deg. C.

Experiment 5. Mix: Same as in experiment 1. Melted in an alundum crucible. Brought to 1450 deg. C. for 3 hours. The melt was very fluid but quiet. This gave 0.38 per cent of the iron reduced. Temperature variation 41 deg. C.

Experiment 6.—Mix: 6 oz. iron oxide, $\frac{1}{2}$ oz. fluor spar, 1 oz. erythrite and 1 oz. soda ash. Melted in a graphite crucible. Held at 1000 deg. for 1 hour and then brought to 1250 deg., where it was held for 2 hours. Showed 11.4 per cent of the iron reduced. Temperature variation at 1000 deg.—82 deg. C. at 1250 deg.—61 deg. C.

Experiment 7.—Mix: Same as in experiment 6. Brought to 1450 deg., and held for 3 hours. This showed 31.4 per cent of the iron reduced. Temperature variation 45 deg. C.

Experiment 8.—Mix: Same as in experiment 6. Melted in an alundum crucible. Brought to 1250 deg. C. for 3 hours. Showed 0.63 per cent of the iron reduced. Temperature variation 23 deg. C.

Experiment 9. Mix: Same as in experiment 6 with the addition of 1 oz. 80-mesh charcoal in an alundum crucible. Held at 1250 deg. for three hours. Showed 86.3 per cent of the iron reduced, but was not melted. Temperature variations 94 deg. C.

Experiment 10.—Mix: Same as in experiment 1 with 1 oz. charcoal added. Held at 1250 deg. for three hours. The melt was more fluid than in experiment 9 and showed 88.8 per cent of the iron reduced, but the iron was not melted. Temperature variation 85 deg. C.

Experiment 11.—A quantity of the mix of experiment 1 without the iron oxide was melted in a platinum crucible in an atmosphere of hydrogen, cooled and weighed. The weight of the material was 21.6076 grams. It was again melted and held for three hours in an atmosphere of oxygen, cooled and weighed. The weight was 21.5937 grams, showing a loss, instead of an increase in weight, as might have been expected from Mr. Amsler's talk and his letter.

From these experiments the following conclusions are drawn: That the mixture of feldspar, bauxite, and lime, as recommended by Mr. Amsler, does not facilitate the reduction of iron from its oxide; that it does not absorb oxygen in any way, nor does it help carbon or other reducing agents to absorb oxygen in any way, except by means of its fluxing action. That any other easily melting flux has the same effect. That any reduction which takes place is entirely due to the action of carbon, and not due to any properties of the mix as reported. That the reaction is not exothermic as reported; in fact it does not show any appreciable change of temperature, during the melt, and that without the carbon no iron is reduced, while if carbon does the reducing, the reaction is endothermic. The total effect of the mix is only one of a flux, and not one which is easily handled. It seems to me that Mr. Amsler has taken this process on faith and not on actual practice as he claims.

Mr. Amsler's process is not a process at all, and I for one am very sorry that the patent laws of our country are so loose, that they will permit the patenting of such a thing, that on the face of it is impossible, and which on trial proves to be a pipe dream, and the exploiting of such things for the innocent investors, who think that if a thing is patented, it is all right.

In the discussion of Mr. Clark's paper Mr. Amsler objected to the phrase that "the exothermic steel process was his process." Mr. Amsler said that Mr. Fogler and not he was responsible for the process. He could not explain why the reactions did not take place in Mr. Clark's experiments. During the discussion Mr. Amsler also quoted Dr. Munroe, of George Washington University, as vouching for the process.

Mr. Philo Kemery, metallurgical engineer of the Crucible Steel Company of America, then presented his report on his own experiments, as follows:

Report by Mr. Philo Kemery

I have made ten experiments with the "exothermic steel" process, following Mr. Amsler's instructions as given in his talk at our former meeting. My experiments with results briefly stated, follow:

Experiment 1.—36 lb. hammer scale, 1 lb. feldspar, $\frac{1}{2}$ lb. bauxite, 1 lb. lime, were all thoroughly mixed and placed in a regular steel melting crucible. The temperature was brought up to a good yellow heat in a small heating furnace. Results: no reaction.

Experiment 2.—The crucible from Experiment 1 with its contents was then placed in a crucible furnace along with a heat. At the end of one hour it was noticed that the crucible was cutting badly, due of course, to the scale and the fluxes. At the end of two hours the crucible was withdrawn, the bottom portion still held together while the top crumbled in the process of drawing. In this experiment 11 lb. of iron was reduced which was to be expected since years ago hammer scale and iron ore were reduced in the same way without the use of the above fluxes.

Experiment 3.—In this experiment, iron ore was substituted for hammer scale as it is much more readily reduced.

80 oz. iron ore, 4 oz. feldspar, 2 oz. bauxite, 4 oz. lime were well ground, thoroughly mixed and placed in a small plum-bago crucible. At the suggestion of Mr. Amsler it was heated in a round cast-iron stove using pulverized coke as fuel. He directed that the coke be piled around and on the top of the crucible so as to insure a reducing atmosphere which was followed out.

Some two or three tests were tried, the temperature being brought up to a good yellow heat for from two to three hours

In all there was found some reduced iron, but in no case was there any evidence of an exothermic reaction. The volume of the contents of the crucible was reduced to about one-half the original in nearly all cases.

Experiment 4.—Later, it was further suggested by Mr. Amsler that a little carbon, say, about 10 per cent, facilitated the reaction, so a new mixture was made up as follows:

No. 1.—40 oz. iron ore, 20z. feldspar, 1 oz. bauxite, 2 oz. lime, 4 oz. charcoal.

No. 2.—40 oz. iron ore, 2 oz. lime, 4 oz. charcoal.

All were ground and thoroughly mixed. Several parallel runs were made by heating in the stove. Crucible No. 2 showed about the same as No. 1. Both contained reduced iron in the form of a spongy mass, but no evidence of any exothermic reaction.

Experiment 5.—Parallel runs with the above mixtures were then made in a heating furnace in which the temperature was raised almost to a white heat with negative results. Beginning with experiment 4 parallel crucibles were run in which No. 1 contained the active fluxes, feldspar and bauxite, while in No. 2 they were left out for comparison of results.

Experiment 6.—Since the heating furnace did not produce as good a reducing flame as is thought necessary, several parallel experiments were tried in a blacksmith's forge using the same formulas as in experiment 4.

Here again the coke was filed all around and over the top of the pot and in 40 minutes the temperature brought up to the melting point of steel.

Crucible No. 1 showed a spongy mass of more or less reduced iron. A glassy slag was formed. The contents were not sufficiently melted to teem. In crucible No. 2 there was less slag, the other conditions being about the same as in No. 1.

The volume was much reduced, the residue or reduced iron from No. 1 could not be differentiated from that of No. 2. No exothermic reaction.

A crucible of steel scrap was then placed in the forge and heated for 40 minutes as near as possible under the same conditions. When removed the pieces of scrap were all fused together. A $\frac{1}{4}$ -in. iron rod was melted at this temperature in about 1 minute, which shows that the temperature was much above that where the exothermic reaction is reported to begin, namely, 1000 deg. C.

The "matte" from experiment 6 was heated in an open-hearth furnace, the crucible being placed on the bank just inside the door of the furnace and examined by tilting the crucible every five minutes. At the end of 35 minutes the contents was boiling. When teemed on the floor 11 grams of metallic iron was separated from the slag. A crucible of steel scrap placed alongside the above melted in 25 minutes.

Experiment 9.—Another crucible of "matte" was heated in the open-hearth furnace at a slightly lower temperature for 35 minutes. A good slag was formed, but when the crucible was teemed a semi-reduced mass of iron was left in the bottom.

The crucible of steel scrap was partially melted.

Experiment 10.—In this experiment three crucibles were used. No. 1.—40 oz. iron ore, 2 oz. feldspar, 1 oz. bauxite, 2 oz. lime, 4 oz. charcoal.

No. 2.—40 oz. iron ore, 2 oz. lime, 4 oz. charcoal.

No. 3.—All steel scrap.

All three were placed in an open-hearth furnace at same time. No. 1 in 55 minutes showed a fine glassy slag, but when teemed there was left the same spongy mass of semi-reduced iron.

No. 2 in 35 minutes developed a little slag with a semi-reduced residue in the bottom that could not be distinguished from that of No. 1. No. 3 was melted in 25 minutes.

These crucibles were tilted over every five minutes for the purpose of examination.

In all of these experiments the crucibles were closely watched, for it is claimed that when the content of the crucible is raised to about 1000 deg. C. the chemical reactions within develop sufficient heat to raise the temperature to that of melted iron. It

is further claimed that when the exothermic reaction begins the content of the crucible is likely to boil over. In no case did I see anything that resembled or approximated these claims.

In a majority of these experiments the contents of the crucible was much reduced in volume. A crust of semi-reduced iron was formed on the top and all around the side the

ONE OF THE PRODUCTS OF EXPERIMENT 10 OF MR. KEMERY

thickness of which depended upon the time and temperature. The results further show that the oxides of iron were reduced about as well without the use of feldspar and bauxite as with. The products of experiment 10 were exhibited to the society in which No. 1 could not be distinguished from No. 2.

General Discussion

Following Mr. Kemery's report Mr. Amsler stated that he himself did not believe at first Mr. Fogler's contentions that he could reduce iron ore to steel by means of his flux. Mr. Amsler re-quoted from his first paper: "This steel was first brought to the writer's attention about a year ago by Mr. George Fogler, the inventor. At that time the claims and descriptions of the process appeared rather absurd and the statements of results were hard to believe. Close investigation of this steel already in use and of the reactions and the theoretical side of the operation led to the conviction that the process has considerable merit." Mr. Amsler again quoted Dr. Munroe, of George Washington University, as endorsing the process.

Mr. Kemery then asked Mr. Amsler whether in the melting this "matte" in an open-hearth steel furnace any difficulty was experienced in the handling of the slag.

Dr. Schluederburg, chairman of the Pittsburgh Section, asked Mr. Amsler if Mr. Fogler would not come down to Mr. Clark's or Mr. Kemery's laboratory and be present while a laboratory experiment was being made.

Mr. Amsler replied that Mr. Fogler was adverse to laboratory experiments and placed no reliance on them. Mr. Amsler said that the material was produced commercially and quoted a case where the Brahm Steel Company had made some Otis elevator shafts in one case where eleven pots of about 100 lb. had been required for one cast.

Mr. Amsler was asked if this flux had not been used some ten years ago in the reduction of copper from its ore.

Mr. Amsler replied that this flux would also apply to copper.

Mr. Kemery reported that in the case where anything like

steel was produced in his experiments, the steel obtained ran 0.134 in sulphur which alone would condemn the steel produced. This sulphur undoubtedly was obtained from the feldspar.

Mr. Amsler questioned as to why the Brahm Steel Company would not furnish a sample of steel for test purposes replied that the Brahm Steel Company did not have a license to make this material and hence would not make this steel or sell this steel to anyone outside of Mr. Fogler.

We are indebted to Mr. Sydney Cornell, secretary of the Pittsburgh section, for the above report of the discussion.

The Willard Gibbs Medal for Dr. Baekeland

The Chicago Section of the American Chemical Society has elected Dr. Leo H. Baekeland, of Yonkers, N. Y., to be the recipient of the Willard Gibbs Medal founded by William A. Converse. The first award was made in 1911 to Prof. Svante Arrhenius, director of the Nobel Institute, at Stockholm, Sweden. The second medalist was Prof. Theodore W. Richards, of Harvard University.

The formal presentation of the Willard Gibbs Medal will be made to Dr. Baekeland at the May meeting of the Chicago Section of the American Chemical Society.

Dr. Baekeland is at present in Europe, but is expected to return early in April.

The jury of award which selected Dr. Baekeland comprised Prof. Alexander Smith, Dr. W. R. Whitney, Dr. E. C. Franklin, Prof. W. A. Noyes, Dr. J. D. Penlock, Prof. G. B. Frankforter, Prof. John H. Long, Prof. Julius Stieglitz, Mr. William Brady, Mr. E. B. Bragg, Mr. S. T. Mather and Dr. G. Thurnauer.

Iron and Steel Market

March developed no material change in the iron and steel markets. The situation has indeed been rather colorless since the first of the year, a definite pace being established and showing no material variation. In brief the history of the finished steel trade has been as follows: Production has been maintained at capacity, but operations were particularly good in March, on account of weather conditions, making March the record tonnage month in the history of the industry. New buying, represented by the closing of contracts, has been at from 60 to 90 per cent of capacity, perhaps averaging 75 per cent. Specifications received against existing contracts have uniformly exceeded shipments, though by only a negligible margin. Realized prices on shipments have slowly increased, through the closing out of old contracts, and in March were only about \$2 a ton below the openly quoted prices on new business.

The course in the pig-iron market has been altogether different from that in the steel market. While the advance in steel prices practically ceased early in October, leaving the market stationary thereafter, pig-iron prices continued to advance until about the middle of December, and only a fortnight or so later evidences of weakness began to appear, these developing into a definite decline which continued through the first three months of this year, making the total decline from the high point in December to date between 75 cents and \$1 a ton, though by no means equally distributed. In foundry iron the declines have averaged fully \$1 a ton, while Bessemer iron has not declined at all, and basic iron has declined only 50 cents.

Thus there has been a divergence between steel prices and pig-iron prices, and again a divergence in the movement of different grades of pig iron, but the latter divergence fits with the former: in other words the strength of the steel market has prevented steel making iron from declining much in sympathy with foundry iron.

The physical situation explains the market movement. Through the building of many furnaces by steel works in recent years the steel works have become more self-supporting, as to pig iron, than ever before. The merchant furnace capacity nevertheless has been increased, chiefly by the building of

furnaces by Lake Superior ore interests, seeking a more certain outlet for their ore than sales in the season to season market. The demand for steel, moreover, has for many years increased more rapidly than the demand for iron castings. The gradually increasing demand last year for all classes of material brought the steel industry to a point in October at which it was operating practically full, but there remained many idle furnaces. Some of these furnaces have been blown in, so that from October to March there was practically no increase in steel works production of pig iron, but an increase of 15 to 20 per cent in merchant furnace production. It is probable that there is now surplus production of merchant pig iron, but this is not certain. The decline in the market could be explained, in part at least, by the conduct of buyers, who are in the habit of buying farther and farther ahead if the market is advancing, but who the moment any weakness develops determine to buy no more iron until their contracts and stocks are entirely exhausted. Thus buyers have been playing a waiting game, sufficient to cause a decline in so open a market as pig iron even were the statistical position wholly in favor of producers. Similar movements do not occur in steel partly because pig-iron markets are local, whereas nearly all steel products are sold on a Pittsburgh basis and partly because the steel interests normally work more in harmony with each other than do producers of pig iron. Pig iron contracts are usually enforced, while steel contracts usually are not enforced if the market goes against the buyer. Hence the steel maker is very anxious to see quoted prices maintained, while the furnaces are relatively indifferent.

Pig Iron

Demand for pig iron throughout the country was very light in March, the chief activity being in low-grade iron for pipe foundries in the East and in basic iron in the Central West. Prices declined in almost all markets, Eastern foundry iron losing 50 cents, and valley foundry iron as much or more. The Southern market dropped 50 cents, to \$13, Birmingham, and there are reports that even that figure has been shaded. Lake Erie furnaces west of Buffalo showed the greatest weakness, quoting prices to distant points, not normally in their territory, such as to undermine prices made by furnaces in such territory. Thus Cleveland furnaces offered iron in Pittsburgh, although at a 50-cent freight disadvantage compared with the valleys, having \$1.40 freight to Pittsburgh against 90 cents for the valleys. Consumers of foundry iron, instead of being tempted by reduced prices, are more firm in their attitude of holding off. In several districts increased inquiry is reported, but such inquiry is obviously for the purpose merely of securing information as to the extent of the drop, consumers being quoted lower prices and yet not buying. In the Pittsburgh-valley district sales of about 30,000 tons of basic iron were effected in March, prices declining slightly from sale to sale, until \$16, valley, was reached for third quarter delivery, against a price of \$16.50 maintained from the beginning of December to the middle of February. The market is now quotable as follows: Bessemer, \$17.25; basic, \$16; No. 2 foundry and malleable, \$16.25; forge, \$15.75, f.o.b., valley furnaces, 90 cents higher delivered Pittsburgh; No. 2 X foundry, delivered Philadelphia, \$17.75; basic, delivered eastern Pennsylvania, \$17.50; No. 2 foundry, f.o.b. Buffalo furnaces, \$16.50; at Cleveland furnaces, \$16; at Chicago furnaces, \$17.25; at Birmingham, \$13. Freight from Birmingham are \$3.25 to Cincinnati, \$4.35 to Chicago, and \$4.90 to Pittsburgh.

Steel

No improvement has occurred in shipments of billets and sheet bars on contracts. Mills having adequate contracts are sheet well supplied, but mills indifferently covered by contract are unable to secure extra tonnage in the market. The United States Steel Corporation has continued to be short of steel, and during March purchased 6000 tons from Butler for consumption at Ellwood City, also taking 15,000 tons in the East and South. The market for such odd lots as are occasionally sold continues to be quotable at \$29 for billets and \$30 for sheet

bars, f.o.b. maker's mill, Pittsburgh or Youngstown. Prices charged on long-term requirement contracts are considerably less, but are advancing. The Carnegie Steel Company on March 20 named prices for second quarter on quarterly adjustment contracts \$1 a ton higher than were named for first quarter.

Finished Steel

There have been further decreases in premiums on finished steel for early delivery, and there is now relatively little of such business except in bars, for which product premiums have rather been tending to increase. For early delivery there are now rarely premiums on sheets, and premiums on plates in reasonable tonnages do not run above \$1 to \$3 a ton at the outside. The East mills are obtaining large premiums on steel bars, sometimes \$4 a ton or more, but in the Central West there are hardly any mill sellers for prompt shipment, and jobbers are obtaining an unusually large amount of business.

In steel manufactures more irregularities have appeared. Rivets have been shaded so much that the quotable market is down \$2 a ton and the same can be said of bolts and nuts. There are slight irregularities in merchant pipe, and prices for fabricated steel on small jobs are considerably lower than in January.

Regular prices at Pittsburgh, unless otherwise stated, are as follows:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.45 cents.

Shapes, 1.45 cents.

Steel bars, 1.40 cents, base.

Steel hoops, 1.60 cents, base.

Common iron bars, 1.65 cents, Pittsburgh; 1.60 to 1.65 cents, Philadelphia; 1.57½ to 1.60 cents, Chicago.

Sheets, blue annealed, 10 gage, 1.75 cents; black, 28 gage, 2.35 cents; galvanized, 28 gage, 3.50 cents; painted corrugated, 28 gage, 2.55 cents; galvanized corrugated, 28 gage, 3.55 cents.

Tin plates, \$3.60 for 100-lb. cokes.

Merchant steel pipe, ¾ to 3-in., 80 per cent off list.

Steel boiler tubes, ¾ to 4½ in., 70 per cent off list.

Standard railroad spikes, 1.85 cents.

Button head structural rivets, 2.10 cents; cone-head boiler rivets, 2.20 cents.

The reduction of stannic oxide to tin can be accomplished by molten metallic zinc, according to a patented process of Zdenko Metzl, of Rouen, France. When metallic zinc is melted in a reducing atmosphere and treated with stannic oxide, tin is reduced rapidly and quantitatively, and zinc oxide is volatilized.

The Dorr Cyanide Machinery Co., Denver, Col., has just issued a new catalog descriptive of the three Dorr machines, classifier, continuous thickener and agitator. The booklet contains 36 pages, and is illustrated with installations of the different machines in various parts of the world. Practical data also are given regarding the operation of the machines, and the results obtained by them. The classifier and continuous thickener are better known than the agitator, the last being a new development.

The launder type of Richards pulsator classifier is the subject of a new Bulletin, No. 1050, just issued by the Denver Engineering Works Company, Denver, Colo. This is a comparatively new development in classifiers, and consists of a settling pocket which is bolted to the launder, a sorting column under the pocket, a hatch below the sorting column and the Richards pulsator valve. It is a single compartment classifier, and one is used for each table in the mill.

The behavior of nitroglycerine when heated has been investigated by Snelling and Storm, (*Technical Paper No. 12*, U. S. Bureau of Mines), who find that the substance begins to decompose at 50 to 60 deg. C. At 70 deg. C. the commercial product gives off nitrous acid after 15 to 20 minutes. Boiling occurs at 145 deg. C., due partly to decomposition and partly to volatilization. Explosion takes place at about 218 deg. C.

Synthetic Ammonia

An account of the Report of Professor Haber which led the Badische Company to take up the Process on a Large Scale

The report on "the technical production of ammonia, from its elements," which was submitted by the inventors, Prof. Fritz Haber and Dr. R. Le Rossignol, to the Badische company three and a half years ago, has now been published in the *Zeitschrift für Elektrochemie* of Jan. 15, 1913 (Vol. 19, p. 53).

Since the report was submitted the Badische company has developed this process on a large scale and in his paper before the International Congress of Applied Chemistry last September (this journal, September 12, Vol. , p. 637, 1912) Dr. H. A. Bernthsen stated that the "problem has now been solved fully on a manufacturing scale and that the walls of the first factory for synthetic ammonia are already rising above the ground at Oppau, near Ludwigshafen-on-Rhine."

Since the report of Haber and Le Rossignol contains a great many technical details which were not given in the paper of Bernthsen, we give here as full an abstract as possible.

Professor Haber and Dr. Le Rossignol first point out that from a commercial viewpoint the production of ammonia from its elements is an exceedingly attractive proposition. The world's demand of ammonia is several hundred thousand tons a year and these are supplied almost completely from nitrogen in coal. In form of 25 per cent ammonium sulphate the ammonia is worth 22.25 cents per kilogram, while the cost of 14/17 kilogram of nitrogen is 1.125 cents and the cost of 3/17 kilogram of hydrogen is 4.375 cents (1 kilogram of ammonia containing 14/17 kilograms of nitrogen and 3/17 kilograms of hydrogen).

In order to determine the best conditions of the synthesis, that is, especially the most favorable temperature and pressure, two points are of chief importance, first, the thermodynamic equilibrium, and, second, the reaction velocity. The thermodynamic equilibrium determines how far at the given temperature and pressure the reaction between the nitrogen and hydrogen gases, forming ammonia, will proceed and where it will stop, and it determines how great the percentage of ammonia is in the final gas mixture of nitrogen, hydrogen and am-

monia, in which the constituents are in equilibrium with each other. The reaction velocity determines how much time will be required between the hydrogen and nitrogen in order to reach the final condition of equilibrium. It is important to note that while the thermodynamic equilibrium depends only on temperature and pressure, the reaction velocity which also depends on these two factors may further be influenced to a very large extent by the use of catalytic agents.

To develop a practical process the conditions of temperature and pressure should, of course, be so chosen as to

yield an equilibrium in which the percentage of ammonia in the final gas mixture is as high as possible. On the other hand, they should be so chosen that the reaction velocity between nitrogen and hydrogen should be as high as possible. But these two conditions are contradictory to some extent. This will be obvious if an attempt is made to use ordinary atmospheric pressure and to select the most favorable temperature at which the reaction should be carried out. If a low temperature is chosen the thermodynamic equilibrium is favorable, since a relatively large amount of ammonia can exist in contact and in equilibrium with hydro-

gen and nitrogen gases, but in this case the reaction velocity is exceedingly low since practically the two gases do not react with each other at all and no catalytic agent has so far been found which would be efficient at temperatures of 300 deg. C. or less. On the other hand, if a high temperature is used the reaction takes place quickly but stops very soon since the equilibrium is reached when only a very small amount of ammonia is formed.

It is evident that to solve the problem ordinary atmospheric pressure cannot be used, but the best conditions of both pressure and temperature have to be selected. Practical considerations have led Haber and Le Rossignol to the conclusion that the temperature should be chosen between 500 and 700 deg. C. If a higher temperature than 700 deg. C. would be chosen the conditions of the thermodynamic equilibrium become unfavor-

FIG. 1.—THERMODYNAMIC EQUILIBRIUM CONDITIONS OF SYNTHESIS OF AMMONIA

able. If temperatures below 500 deg. C. would be chosen the reaction to be complete would require too much time and too large an amount of catalytic agent. Within the limits of 500 and 700 deg. C. the conditions of the thermodynamic equilibrium are given in Fig. 1.

This diagram gives in the straight line the equilibrium constant and in the two curves marked $P=200$ atmospheres and $P=100$ atmospheres, the percentages of ammonia in the final gas mixture which represents thermodynamic equilibrium. For instance, with a pressure of 200 atmospheres the final gas mixture in which its constituents are in equilibrium contains 18 per cent ammonia at 500 deg. C., 8 per cent ammonia at 600 deg. C. and 4 per cent ammonia at 700 deg. C.

While these percentages are satisfactory, they are not high enough to conduct the process in such a simple way that the gas would be compressed, passed over the catalizer, whereupon the ammonia formed would be absorbed, and the balance of the gas would be wasted. The waste would be too great. The process must, therefore, be conducted in such a way that after the ammonia is recovered from the final gas mixture, the remaining gases, together with a fresh supply of H and N gases, are subjected again to the action of the catalytic agent. This problem has been solved by Haber and Le Rossignol by devising a partial cyclic process for the movement of the gas, the ammonia being formed at a high temperature and the ammonia being removed from the gas mixture in form of liquid ammonia at a low temperature, the remaining gas mixed with fresh gas being then subjected again to the action of the catalytic agent, and so on.

Care must be taken not to use too low a temperature for the removal of the ammonia from the gas mixture, since there

Practical experience with liquid air indicates that "regeneration of heat and cold" becomes particularly efficient and easy when using high-pressure gases. The same has been found to be true by Haber and Le Rossignol in their experiments.

FURNACE CONSTRUCTION

Both quartz and metallic containers were used in their experiments. Above 700 deg. C. and with pressures up to 50 atmospheres Haber and Le Rossignol used quartz tubes, but did not dare to use them at 100 and 200 atmospheres. Later on when they found that it would be advantageous to use temperatures below 700 deg. C., Haber and Le Rossignol developed various metallic furnaces, several types of which were heated from the inside by electric resistance wire. Their construction is described in detail and illustrated in the report.

Later on it was found possible to use so low a temperature that it was sufficient to use iron containers heated from the outside. The continuous production of ammonia became possible by means of a simple sort of test tube of steel, shown in Fig. 2. A steel cylinder with 6 mm. inside diameter and a 4 to 5 cm. length contains the catalytic agent. The inside space slants outside at the top, forming a cone, so that a steel stopper can be pressed into it, also of conical form. The angle of the cone of the stopper (16 deg.) is less than the angle of the cone in the cylinder head (20 deg.). By turning the screw as shown in the illustration the apparatus can be closed absolutely air tight.

The nitrogen and hydrogen gases are introduced through a steel capillary tube which reaches down to nearly the bottom of the reaction chamber. The gaseous products of the reaction leave the chamber through another capillary tube at the top.

About 2 or 3 grams of osmium are used as catalytic agent in this apparatus. To heat it, the whole apparatus is placed in a fused salt-peter bath and the nitrogen-hydrogen gas mixture is passed under high pressure slowly through the apparatus. With a bath temperature of 555 deg. C. and a pressure of 83 atmospheres the percentage of ammonia in the gases passing out of the apparatus was 5 per cent, which is very nearly equal

FIG. 2. — SIMPLE FURNACE FOR SYNTHESIS OF AMMONIA

FIG. 3. — ARRANGEMENT OF EXPERIMENTS WITHOUT GAS CIRCULATION

would be danger of the ammonia being precipitated in solid form and clogging the gas pipes. With temperatures not lower than -75 deg. C. this danger is avoided.

to the amount corresponding to thermo-dynamic equilibrium.

Several types of furnaces, electrically heated

from the inside, are described, the construction being given in considerable detail and in various diagrams in the original report. Especially if electric heating is employed it is important not to lose the heat, but to regenerate it. The use of heat regeneration has also the advantage that the gases which leave the catalyzer at a high temperature have a low temperature when they reach the apparatus exit.

The method of heat regeneration employed by Haber and Le Rossignol is very simple, the gas mixture being forced to pass through prescribed passages, the heat regenerator con-

In the second series of experiments the technical practicability of the whole process as a continuous process had to be tested in that the gas mixture coming from the furnace had to be cooled, the ammonia removed, and the remaining gases returned to the furnace, etc., in continuous operation.

The arrangement of the first series of experiments (with gas circulation) is shown in Fig. 3. The mixture of hydrogen and nitrogen gases is passed from the steel container *A* through a copper capillary tube into an iron cylinder *B* filled with palladium asbestos and heated in a salt-peter bath. On account of the combination of the last traces of oxygen in the gas with hydrogen some water is formed which is removed by passing the gas through calcium chloride *C*. The gases then pass to the furnace *E* in which *F* is the thermo-element, *H* the heating wire, and *G* the cooling water.

The mixture of hydrogen and nitrogen gases and of the ammonia formed in the furnace *E* passes out through a thin steel capillary tube into the iron tube *K* which is subjected to cold so as to liquefy the ammonia. To the iron tube *K* is connected at its bottom a glass tube *I* of thick walls in which the liquefied ammonia accumulates and can be measured and drawn off at will.

This refrigerating apparatus *K* for the liquefying of the ammonia was not used in all experiments. In the majority of the experiments the liquefier *K* was disconnected and the gas mixture passed from the furnace *E* directly into the meter *M* which measured the velocity of the gas. The determination of the ammonia in the gas mixture could be carried out in a great many cases by an optical method (apparatus *N N*) by using the Rayleigh gas interferometer of Carl Zeiss, according to the method proposed by Haber for the analysis of furnace and mine gases.

The arrangement of the second series of experiments (with gas circulation) is shown in Fig. 4. The hydrogen and nitrogen gas enters at *A* into the furnace *F* in which the ammonia is formed, and the ammonia, nitrogen and hydrogen gas mixture leaves the furnace through the capillary coil *B*, which is embedded in cooling water. The gases pass two valves, pass through the dryer *C* (where any traces of water are removed) and then enter the "cold regenerator" *D*. This consists of a system of three copper capillary tubes wound as shown in the detail sketch *X*. The gases having been strongly cooled in the regenerator, enter the liquefier *D* in which the ammonia is liquefied. The level of the liquid ammonia can be seen at *E*.

The liquid ammonia may be drawn off through *F*. The hydrogen and nitrogen gas mixture from which most of the ammonia has been removed by liquefaction, is then returned to the cold regenerator *D* and is then forced through the pump *P* back into the furnace *F*, while a valve permits to introduce new hydrogen and nitrogen gases simultaneously into the furnace.

All the constructional details of the pump and the other high-pressure apparatus were worked out by Professor Haber and Dr. Le Rossignol themselves and the apparatus were built by them with the aid of the machinist of their laboratory. Since doubts had been expressed concerning the practicability of working

FIG. 4 ARRANGEMENT WITH GAS CIRCULATION

sisting essentially of a great many capillary steel tubes held together by perforated plates at the two ends.

The catalytic agent was placed into the catalytic chamber in a manner which is acknowledged to be rather primitive. Upon the vertical iron tube which contained the thermo-elements, wire-net disks were fixed so as to divide the catalyzer room into a number of chambers one above the other. Some osmium was sprayed into each of these chambers, asbestos being employed to prevent the very fine osmium powder from dropping down through the wire net or from being blown away. The osmium filled only a very small part of the chambers.

Arrangement of Experiments

Two kinds of experiments were made. In the first series of experiments the object was simply to determine the efficiency of different catalytic agents and for this purpose it was sufficient to pass the mixture of hydrogen and nitrogen gases (in the proportion of 3 to 1 by volume) through the furnaces and determine the ammonia that was formed.

with moving gases under high pressure, the authors emphasize that in their work of several years there was never a break of any apparatus or any appreciable trouble.

Catalytic Agents

In investigating the properties of the different elements as to their ability to act as catalytic agents in the formation of ammonia, Professor Haber and Dr. Le Rossignol used the periodic system as the leading idea. It was known that *manganese* and *chromium* are catalyzers. Since in the group containing manganese the elements with highest atomic weights are missing, no advance was possible along this line. On the other hand, in the group containing chromium the two elements with highest atomic weights are tungsten and uranium. In fact the authors obtained a fairly good success with *tungsten* and surprising success with *uranium*.

Uranium may be used in the form in which it is obtained in the electric furnace; it only needs to be roughly crushed. For if it is then slowly heated in the high-pressure gas mixture of one volume gas mixture and three volumes hydrogen, it disintegrates by itself into a fine powder. Commercial metallic uranium, made by Kahlbaum, was used, also commercial metallic uranium, made by de Haen, and uranium made by Moissan's method.

Among the different experiments with uranium, described in the report, is the following in which the furnace, Fig. 2, described before, was used. Uranium was filled into the furnace in form of pieces of pin-head size. The furnace was heated in the saltpeter bath, which also contained an iron tube in which was the thermo-element in porcelain tubes.

An excess pressure of 125 kg per square centimeter was used with a gas mixture of three volumes hydrogen and one volume nitrogen.

Velocity of gas	Temperature	Percentage of NH ₃
32 liters per hour	570 deg. C.	5.65
25.7 liters per hour	595 deg. C.	6.54
9.5 liters per hour	496 deg. C.	9.1
2 liters per hour	503 to 493 deg. C.	11 to 11.9

In the periodic system manganese has as its left-hand neighbor chromium and as its right-hand neighbor iron. *Iron* is also a catalytic agent for ammonia formation. Below the iron in the same vertical column in the periodic system, we find ruthenium and osmium. Both can be produced in very finely powdered form by similar methods. Ruthenium, however, did not prove a very effective catalytic agent, while *osmium* is very effective. It is notable that in both the iron group and the chromium group of the periodic system the elements with the highest atomic weight—uranium and osmium respectively—are the most effective catalytic agents.

From the different osmium experiments described in the report only the following one may be mentioned, in which a osmium powder layer of 14 mm length and 4.5 mm diameter was used:

Velocity of gas	Pressure	Temperature	Percentage of NH ₃
20 liters per hour	156 atm.	592 deg. C.	4.75
10 liters per hour	156 atm.	572 deg. C.	5.91
1.5 liters per hour	174 atm.	550 deg. C.	7.9
1.5 liters per hour		521 deg. C.	9

The conclusion of the report is an account of a test of longer duration with gas circulation, made to show that the continuous operation of the process with liquification of the ammonia and with the return of the remaining gases into the furnace meets with no difficulties. The heat and cold regenerators proved very efficient.

New Polariscopes Tube.—The Bausch & Lomb Optical Company of Rochester, N. Y., has just placed on the market a new polariscopes tube, constructed after the design of Frederick Bates, of the U. S. Bureau of Standards. It is a scientifically designed tube suitable for nearly all polariscopic work and especially adapted to sugar polarizations. It has been adopted by the Bureau of Standards.

The Western Metallurgical Field

New Ore Discovery in Colorado

It has been so many years since a promising discovery of ore was made in a new district in Colorado, that the recent announcement of such a discovery in Eagle county has attracted more than usual attention. The scene of the new discovery is on Brush Creek, in the vicinity of the Mount of the Holy Cross, where an earlier discovery of gold and silver ore a number of years ago gave prominence to the camp of Fulford. On account of the difficulties encountered in prospecting and transportation, nothing of importance developed from the earlier discovery; but conditions are now more favorable, and it is probable that the coming spring and summer will find this district thoroughly prospected. At present the snow is too deep for widespread prospecting.

The ore is unlike anything thus far known in Colorado. In appearance it is a grey sandstone, containing minerals of silver which are variously reported to be chloride, bromide and sulphide. Assays indicate the presence of silver in large quantities, several hundred ounces per ton. The richest ore shows bluish spots which, when heated under the blow-pipe or in a muffle, yield metallic silver. A peculiarity of the ore is that some of it contains vanadium in small quantities, say about 1½ to 2 per cent V₂O₅. Should later development show that there is a considerable deposit of this kind of ore, a nice metallurgical problem will be presented to those who ultimately mine and treat it. Such a content of vanadium is not appreciably lower than that of some ores which are treated for this metal alone, and it should not be neglected in this high-grade silver ore. This is a condition which should be recognized before too much of the ore is smelted for the recovery of silver alone, in which event the vanadium would be lost in the slag.

Smuggler-Union vs. Liberty Bell

In June, 1912, the suit of the Smuggler-Union Mining Company against the Liberty Bell Gold Mining Company, both of Telluride, Colo., was tried in the United States district court in Denver. The plaintiff alleged wrongful extraction of ore by the defendant. The result of the first trial was favorable to the plaintiff company which was awarded damages in the sum of \$403,000. The case was appealed by the defendant, and was later heard by the United States Circuit Court of Appeals, sitting in St. Louis. This court affirmed the decision of the lower court on March 3, 1913. It is expected that this decision will be final unless the Liberty Bell company can show error sufficient to carry the case to the United States Supreme Court.

Copper Smelting Resumed at Tooele

During the labor strike in the Bingham district, Utah, last fall, the International Smelting & Refining Company ceased smelting copper at its plant at Tooele, Utah. This action was necessitated by the closing of several mines from which the supply of copper ore was received. Since that time the conditions have improved and are again normal, and the International company is again smelting copper concentrates, with no prospect of further interruption. In the lead smelting department of this plant, four blast furnaces are now in operation.

Consolidated Mercur to Close

For the past two years the annual reports of the Consolidated Mercur Gold Mines Company, Mercur, Utah, have foreshadowed the probable necessity of ceasing operations unless conditions improved materially. The shareholders were asked to authorize the directors to dispose of any or all of the property, which authority was granted. It appears that conditions are not improving and that the famous old mine and mill will be closed within a month or so. This act will close the career of a company which, through its technical staff, contributed greatly to the progress of the cyanide industry, particularly through the invention by George Moore of the vacuum filter.

Notes on Chemistry and Metallurgy in Great Britain

From our Special Correspondent.

Annealing Muffles

At the February meeting of the Birmingham Section of the Institute of Metals Mr. E. H. WALL read a paper on "Annealing Muffles," which dealt with the improvements made in muffles during the last fifteen years or so. The fire-boxes were now made smaller than they were formerly and the flues were arranged to distribute the heat better along the sides and under the beds, while the combustion was more perfect; and as the muffle was enveloped with heat there was an economy in fuel. Cross-fired muffles could be got to work more rapidly than end-fired muffles, and the temperature was maintained with greater regularity. The best arrangement for a muffle was one in which the flame, after passing the bridge and bed, went into a series of graduated portholes opposite to the fire-box; and, after passing these portholes, the waste gases entered a flue under the bed, traveled round the muffle two or three times, according to its width, before making their way into stack. There was still a great deal to be done in improving economical appliances, particularly with regard to gas-firing. At the present time 1.75 cwt. to 2 cwt. of coal was consumed in the gas producer for 1 ton of iron annealed, as against 1 ton of coal to anneal $1\frac{2}{3}$ ton in former times; but even now the theoretical heating was a long way from being attained. If it could be attained 1 ton of coal would heat 30 tons of iron to a welding heat. If the annealing point of copper were put at 1400 deg. Fahr., then 133 heat units would be required to raise 1 pound to that temperature, or 1 ton of coal would be enough to anneal 90 tons of copper. It was not probable that this ideal would ever be attained, but modern muffles had brought down the consumption of fuel by 30 to 50 per cent.

The Institution of Mining and Metallurgy

At a recent meeting of the Institution, papers giving a historical sketch of the Copper Queen Mines at Arizona and dealing with the varieties of ores and methods of treatment, as well as the geology of the Bisbee deposits, the power plants and the reduction works, were presented by Dr. JAMES DOUGLAS, Mr. ARTHUR NOTMAN, Mr. CHARLES LEGRAND and Mr. G. B. LEE.

From Mr. Legrand's paper it appears that the plant at Bisbee consists of five water-tube boilers, with super-heaters and economizers, each of 407 hp, which were fired with California crude oil the thermal value of which was about 18,500 B.t.u. per pound. The pressure of the boilers was 155 lb. per square inch, and the super-heater raised the steam to a temperature of about 440 deg. Fahr. There were three two-stage air compressors, two of which were driven by compound steam engines and delivered about 3500 cubic feet of air per minute, and the third was driven by a triple-expansion, four-cylinder engine and put out 7000 cubic feet per minute. The compressed air at 90 lb. per square inch worked five direct-motion hoists, two geared hoists, some hundreds of air drills and machine tools, some air-jet blowers and some small hoists. Three 500-kw vertical steam turbo-generators supplied three-phase current at 2300 volts, 60 cycles, and part of it was transformed down to 260 volts direct current by two 200-kw rotary converters. Several motor driven hoists were in use and all the pumps were worked electrically, while there were eleven locomotives underground, the largest of which weighed about 7 tons.

At Douglas eight boilers were of 500 hp each, with economizers similar to those at Bisbee; and four were of 520 hp, more than 400 yards distant from the boiler house, and utilized the waste heat from the reverberatory furnaces, working at 180 lb. per square inch to compensate for loss of pressure in the long steam main. There were eleven blowers driven by tandem compound engines, and six of these delivered 300 cubic feet per revolution, and the other five 200 cubic feet per revolution; five blowing engines for converters each delivered

6000 cubic feet of air per minute, and one engine 12,600 cubic feet per minute. There were four 400-kw, d.c., 260-volt generators which drove from 50 to 60 motors, 7 cranes and 14 locomotives; and two 750-kw mixed pressure, turbo-alternates supplied three-phase currents at 2300 volts, 60 periods, which was transformed to 44,000 volts to supply current to a mine 67 miles off.

Mr. G. B. Lee said that the original plant put down in 1902 at the reduction works at Douglas consists of five blast furnaces and four converters, and that plant was duplicated in 1906. The furnaces and converters were arranged on the opposite side of a 60-ft. crane-way, and the re-lining plant was at one end of the main building, which measured 900 ft. x 150 ft. The ores were stored in rock-walled pits, 800 ft. long, 38 ft. wide, and 11 ft. in depth.

Formerly the smelting mixture gave mattes with fully 45 per cent of copper, but gradually changes had been made and the matte was now only from 30 to 35 per cent. A further increase in the proportion of sulphide ores was indicated, and the smelting mixture was becoming finer and less suitable for blast furnaces. The altered conditions necessitated a change in the plant and an enlarged capacity, and consequently six 18-ft. McDougal roasters and two reverberatory melting furnaces, each 91 ft. x 19½ ft. were put down in addition.

Previously the whole of the smelting had been carried on in blast furnaces; and the fineness of the charge together with much alumina in the ores made treatment difficult, while large quantities of dust resulted from the disintegration of the pyrites and the fine concentrates. It was found that the loss of metal in the slag did not amount to the metallurgical loss; and the waste appeared to be due to dust going away with the smoke, but as the volume of the smoke was a million cubic feet per minute, bag filtration was impracticable. Experiment demonstrated that when the smoke was passed through a chamber at 150 feet per minute or less the fine dust settled at short distance, and by introducing wire screens 3 ft. apart an equal settlement was obtained at twice that velocity, and the section of the chambers could be considerably reduced. The screens were so contrived that there were no direct channels through the chamber; and the arrangement was the very opposite of the old system of passing the gases at a high velocity through long flues.

The Iron and Steel Institute

The annual meeting of this Institute will be held in London on May 1 and 2 at the Institution of Mechanical Engineers. The Bessemer medal will be presented to M. Adolphe Greiner, director of the Société Cockerill, of Seraing. Arrangements are in progress for holding the autumn meeting at Brussels.

The Society of Chemical Industry

Two departmental committees of the Home Office were appointed in 1911 to investigate the danger attaching to the use of lead compounds in paints for buildings, vehicles and other purposes; but up to the present they have not presented any report.

Professor H. E. ARMSTRONG and Mr. C. A. KLEIN have recently submitted a paper to the Society of Chemical Industry on "The Behavior of Paints under the Conditions of Practice, with special Reference to the Aspersions cast upon Lead Paints." The authors investigated the contention that illness resulting from living in freshly painted rooms and the bad effects felt by painters were due to volatile compounds of lead, and their experiments led to the conclusion that suspended dust and not lead vapor was the cause; and that earlier experimenters had failed to adequately safeguard against dust being carried forward. With regard to the statement recently made by Professor Baly that noxious organic vapors were emitted during the drying of paints, the authors were satisfied that the ill-effects generally experienced in freshly painted rooms were produced by turpentine vapor, and that symptoms commonly attributed to lead poisoning were simply the effects of turpentine. They were of opinion that the dangers attending the use of lead compounds in paints were merely mechanical dangers of which the chief arose from dust; and that painters ran very

little risk of harm if production of dust were duly prevented.

On the question of the comparative qualities of the materials used as white paints they considered that for outside use, where rain and the impurities always found in town air had access to the painted surfaces, lead paints only were suitable. Zinc paints were not adapted to outside work, but were very serviceable for interior use.

The Institute of Chemistry.

Mr. W. J. A. BUTTERFIELD delivered his second lecture on "Chemistry in Gas-Works" on January 31, when he dealt mainly with impurities, their effects on plant and fittings, and methods of purification. The question of by-products, manufacturing costs, work analyses, efficiency of burners for lighting and heating, further requisite chemical research and the qualifications and training of a gas-works chemist were also considered.

The obstruction caused by the deposition of one hundredth part of a pound of naphthalin in a main was experimentally demonstrated; and the processes employed for the recovery of ammonia, the removal of sulphuretted hydrogen, and cyanogen were described and materials exhibited. In connection with the elimination of sulphur impurities remaining after the removal of hydrogen sulphide, the lecturer referred to the reintroduction in London gas-works of the heated contact-substance process for separating carbon disulphide first proposed by Dr. A. Vernon Harcourt more than 40 years ago. Physical tests of tar and pitch were of little value because their physical properties altered with aging, and the nature and extent of the changes could only be ascertained by chemical analysis. The calorimetry and photometry of gas were demonstrated, and the evolution of the modern 10 c.p. Harcourt pentane standard lamp was illustrated by five successive specimens. The lecturer said that he had made comparative tests of about 150 Harcourt pentane lamps and had never found a greater divergence than 0.2 per cent, except where constructional faults existed. The disturbing effects of variations in atmospheric conditions on photometric measurements were discussed.

Transmutation or Expulsion

The general opinion among practical scientists is that Professor Sir J. J. Thomson has effectually disposed of the supposed conversion of hydrogen into helium and neon by Sir W. Ramsey, Professor N. J. Collie, and Mr. H. Patterson. There can be little, if any doubt about the correctness of Professor Thomson's view that the helium and neon are occluded in and are expelled from the electrodes, and possibly also the glass, because he found that these gases ceased to be evolved after a few days, but were again in evidence when fresh electrodes were substituted. If the transmutation claimants knew of Thomson's results before their papers were made public, it is rather surprising that they should not have withheld their communications until they could establish their case on a firmer foundation.

Engineering Imports and Exports

The returns issued by the Board of Trade for the month of January show a satisfactory all-round improvement in the trade in engineering materials and products as compared with January, 1912—the only decrease being in imports of electrical goods. Iron and steel, including manufactures, were imported to the value of £1,469,352, an increase of £390,759, and were exported to the value of £4,827,729, an increase of £473,491. Imports of other metals, including manufactures, amounted to £2,938,770, an increase of £184,530; and exports reached £1,272,040, an increase of £315,174. Imports of electrical goods totaled £136,192, a decrease of £3,804; while exports touched £368,618, an improvement of £93,527. Imports of machinery were of the value of £673,727, and show an increase of £158,780; and exports went to £3,112,474, an increase of £415,832. Imports of new ships are put at only £1,303, which amount however, is £1,246 better; and exports rose to £490,425, an increase of £307,203.

Market Prices, February, 1913

Copper opened at £69. The decline in price which has been

continued this month, has followed the same slope from Jan. 14th, dropping rather more sharply about the middle of the month. It was £66 on the 6th, £64 on the 18th, and since rather firmer, closes £64.17.6.

Tin opened at £230 and took a sharp and heavy drop to £220 on the 6th. It then recovered to £224.10 (10th) and fell away more slowly to £217 (18th), recovering to £219 on the 20th, but falling again to £213 by the 24th, touched £220 on the 26th, and closes £218.

Hæmatite, opened 81/3 and remained steady till the 14th, when it dropped to 80/6 in three days. Kept at this price till the end of the month.

Scotch Pig opened 71/3, and has been exceptionally uneven, being practically the same price on the 11th, and dropping to 65/- by the 18th, closed better at 66/7½.

Cleveland was 65/9 at the end of January and remained about 65/- till 13th, when it dropped away 4/- in five days reaching 60/3 on the 18th. It has since improved slightly, closing 61/-.

Lead opened £16.17.6 and remained firm till mid-month, after rather lower, £16.12.6 on 18th, recovering to £16.17.6 on the 20th, but closing £16.12.6.

The new Van Ryn Deep mill on the Witwatersrand in South Africa, will be equipped with 80 stamps of 1000 lb. weight, eight tube mills each 16 ft. 6 in. by 6 ft., sand leaching tanks and a Butters slime filtering plant. The estimated capacity of the stamps is 20 tons per day, or 40,000 tons per month of twenty-five working days.

Mexican smelting plants of the American Smelting & Refining Company, at Matahuila and Velardena were compelled to close for a time during February on account of shortage of fuel, caused by interruption of traffic. The company's other smelters at Monterey, Chihuahua and Aguas Calientes have been running without interruption.

Recent Chemical and Metallurgical Patents

Electric Furnaces

Means for Joining Electrodes.—The managers of the electrode factory of Gebr. Siemens & Company, Lichtenberg, near Berlin, in Germany, EDUARD VIERTEL and HERMANN VIERTEL, have improved the method of joining two tapped electrodes together with true centers. Screw-threads can be made exactly in the electrodes with very great difficulty only and, as a rule, the screw-threaded nipples are made a little smaller than the appertaining screw thread. On account of the play between the nipple and the tapped end, the joined electrodes are frequently not in alignment. To improve this condition the ends of the electrodes are provided with cylindrical, conical or otherwise shaped centering means, for example, projections or recesses. Fig. 1 shows the wrong way of joining electrodes. Fig. 2 shows an annular ring projecting from No. 2 electrode and fitting into the corresponding recess of 1 electrode. In Fig. 3 both electrodes 1 and 2 have recesses, and a centering annulus is constituted by a separate member 4, which exactly fits the two recesses. These means allow to bring the electrodes into exact alignment. (1,049,624, Jan. 7, 1913.)

Carbon Electrode for Electric Furnaces.—Mr. BERTHOLD REDLICH, of the Planiawerke, Ratibor, Germany, has invented a new form of carbon electrode with metallic core. When metal, and especially iron, is inserted into the electrode before burning, it absorbs carbon and becomes brittle. A better contact is obtained by casting molten metal, or metallic alloys, into the hollow spaces provided in the electrode. In doing this care has to be taken to give the metal such a shape that the contraction during solidification does not separate it from the carbon. The drawings in Fig. 4 illustrate without

The process consists in subjecting the surface of the fabric or screen to the action of a sand blast, which, together with the material used, is so regulated that only the heavy exterior coating of the fabric is penetrated. The inventor claims that this process does not cause the deterioration in the fabric such as arises from the use of acid baths; also that the cost of renewals and repairs will be less than with the latter method.

further explanation various ways of accomplishing this result. (1,048,581, Dec. 31, 1912.)

Gold and Silver.

Cleaning Filter Fabrics and Screens.—The adhesion or precipitation of solids on filter cloths and screens reduces their efficiency, and necessitates occasional cleaning. An improved method of cleaning these devices is proposed by Mr. MAYNARD J. TROTT, of Colorado Springs, Colo., the patent being assigned to the Dorr Cyanide Machinery Company, of Denver, Colo.

The method has been demonstrated on screens and filter fabrics in actual use. (1,052,101, Feb. 4, 1913.)

Lead, Zinc and Copper.

Roasting for Magnetic Separation.—The customary method of roasting mixed sulphide ores for subsequent magnetic separation of the iron, consists in freely exposing the ground ore to an oxidizing flame or heat for a period of several hours. In a process proposed by Mr. JAMES B. ETHERINGTON, of Winthrop, Mass., there is a radical departure from the old method, in that the ore is roasted in a practically non-oxidizing atmosphere, at a temperature that is precisely controlled, and for a brief time. All particles of the ore are subjected to the same degree of heat for the same time, and loss by volatilization is avoided. By avoiding a strong draft through the furnace, a minimum of dust is carried out of the stack.

The furnace is shown in Fig. 5. It consists of an unlined cylinder 7, approximately 6 ft long and 3 ft in diameter. It is practically surrounded by a hood 41, through which cooling air may be drawn by a fan not shown, but placed above the outlet 42. A hydro-carbon burner 10 is placed at the end of the furnace, through which oil and sufficient air to cause complete combustion, are admitted. A drying and preheating cylinder 24 is attached to the furnace, and both have baffles 22 on their interior surfaces for the purpose of causing the ore to fall in

a cascade through the flame. The products of combustion escape by the stack 32, and the roasted ore is discharged through ports 17 adjusted by gates 20. The entire mechanism is supported on rollers and adapted to be rotated by a worm gear.

In operation, the ore is fed through the hopper 30 and travels downward through the furnace owing to its inclination. On reaching the furnace chamber, the particles are subjected to a non-oxidizing heat caused by the blast of oil and air which

FIG. 5.—FURNACE FOR MAGNETIC ROASTING

is directed onto the wall of the furnace and caused to swirl therein. The rate of feed and size of ports are so adjusted that the ore remains in the furnace for only a few minutes, whereupon it is sufficiently magnetized to enable profitable magnetic separation to be made. The inventor claims that longer time or more oxidizing conditions are not necessary, and that if employed they only cause undue oxidation and volatilization of the constituents of the ore. (1,051,494, and 1,053,486, Jan. 28, and Feb. 18, 1913.)

Method of "Amphidizing" Copper Ores.—In describing the apparatus devised for carrying out his process of rendering the copper in ores soluble, Mr. CHARLES S. BRADLEY, of New York City, gives the following definitions: An "amphigen" is an element which combines with metals to form either an acid or a base, as for example oxygen. An "amphid" is a salt of an acid and a base, each of which contains an "amphigen," as for example copper sulphate, $\text{CuO} \cdot \text{SO}_3$. The apparatus which is used to form the "amphid," is called the "amphidizer."

The inventor proposes by amphidizing to convert the copper contents of ores into soluble form, such as copper sulphate, and then separate the latter from the gangue by solution, later precipitating the copper. His process of amphidizing is continuous in operation. The apparatus consists of a rotary cylinder with feed and discharge at the same end, the former being at the axis of the cylinder and the latter at the periphery. Heat is applied by any suitable burner placed at the end of the cylinder opposite the feed and discharge end. The

FIG. 6.—PERSPECTIVE VIEW OF ELECTRIC ZINC FURNACE

ore advances through the cylinder by one set of passages and returns by another. This is accomplished by subdividing the reaction space transversely into a number of reaction chambers, the alternate chambers being connected by bridging passages so inclined that the crushed ore advances by gravity as the drum rotates. The intermediate chambers are connected by

bridging passages inclined the other way so that the crushed ore returns by the action of gravity as the drum rotates.

By this arrangement the returning amphidized ore transfers its heat to the incoming ore, and a regenerative effect is produced. This results in an even distribution and regular heat which is so essential causing chemical reactions requiring a definite and steady temperature. In this case the temperature is maintained at about 550 deg. C., or between the dissociation temperatures of iron and copper sulphates. In some cases the heat of reaction will be sufficient to maintain the proper temperature, and it may be necessary to use artificial cooling to prevent the temperature rising too high. (1,052,793, Feb. 11, 1913.)

Electric Zinc Furnace.—In Figs. 6 and 7 are shown two views of a form of electric furnace for the reduction of zinc ores, devised by PETER E. PETERSON, of Butte, Mont. As Mr. Peterson is reported to have made some successful experiments on the electric reduction of the zinc ores of Butte, his furnace is interesting. The furnace consists of a smelting retort 1 in

FIG. 7.—LONGITUDINAL SECTIONAL VIEW OF ELECTRIC ZINC FURNACE

which the material under treatment is volatilized by an electric current passing between electrodes 2 and 3. The latter is hollow and surrounds the feed pipe through which ore is introduced into the furnace. The condenser consists of a vapor chamber 5 connected with condensing tubes 7, which extend downwardly to a spelter chamber 8. The tubes are surrounded by a wind box through which cooling air is forced by a fan, entering both sides of the condenser chamber through ducts 11 and 11a. After circulating around the condenser tubes, the air is discharged through ports 12. Uncondensed fumes and vapors are discharged from the condenser through vents 14, leading into the duct 15. The spelter condenses in the tubes 7 and settles into the chamber 8, from which it may be withdrawn through a tap 16. Suitable covers for the condensing tubes are provided as at 17 and 18. It will be noticed that the zinc vapors and cooling medium pass in the same direction, an arrangement which the inventor says has been found highly effective. (1,051,512, Jan. 28, 1913.)

Chemical Industry.

Extracting Chlorine, Iodine and Potassium Hydroxide from Seaweed.—Messrs. FRANK K. CAMERON and RICHARD B. MOORE, of Washington, D. C., and Indianapolis, Ind., respectively, have patented a method of recovering useful products from the ash of seaweed and other marine forms of algae, and have permitted the use of the process by any person in the United States, without the payment of any royalty.

According to one method of treatment, the ash of seaweed is lixiviated with water, the solution drawn off from the solid matter and evaporated to a point where the less soluble salts begin to crystallize. The mother liquor then contains all the soluble iodides and some of the chlorides. It is then elec-

tolized in the anode compartment of a diaphragm cell, whereupon chlorine and iodine appear at the anode and potassium hydroxide at the cathode. The chlorine which escapes can be collected, and the iodic acid which is formed can be reduced to iodine by treatment with ferrous sulphate and sulphuric acid.

In a second method, the ash is stirred into water in the anode compartment of a cell. The soluble salts pass into solution, and the same changes occur on electrolysis as described in the first method. (1,051,984, Feb. 4, 1913.)

Iron and Steel.

Manganese Steel.—Mr. HENRY D. HIBBARD, well-known by his research work on impurities in steel, has been granted the following patent for making manganese steel. The object is to utilize manganese steel scrap without material loss of the manganese present in the scrap. If steel scrap containing from 11 to 14% manganese would be charged and worked in the ordinary way in open-hearth furnaces, nearly all the manganese would have to be oxidized before any carbon could be eliminated. This loss can be avoided by melting the manganese steel scrap while it is covered by a bath of decarbonized iron. The latter protects the iron from oxidation while fusion is proceeding. The process can be carried out in an electric furnace. The ordinary charge of an open-hearth furnace can, for instance, be worked down to 0.15% carbon, and the manganese steel scrap thrown into this bath, or the scrap can be heated in the furnace to not more than red heat and then be covered with molten iron of the above carbon contents. When using an electric furnace the latter will be provided with auxiliary heating means. The scrap which is again heated to not more than red heat will be covered with the molten iron, and the melt completed by the application of the electric heating element. When producing manganese steel the small unavoidable loss and the manganese required by the iron have to be added in the form of ferro-manganese. (1,051,840, Jan. 28, 1913.)

Tunnel Furnace.—Mr. ARTHUR RAMEN of Helsingborg, Sweden, applies certain improvements to tunnel furnaces of the canal type, such as are used for the burning of ore briquets at high temperatures and for other similar purposes. The wagons or movable hearths used to carry the material to be treated through these furnaces had a comparatively short life due to the disintegration of the covers and linings of the hearths. This trouble is overcome by providing, in the side walls of the furnace, overhanging portions beneath which the sides of the hearths pass in traveling through the furnace. These overhanging portions are made of hollow tiles and adapted to cooling. The details can be seen from the accompanying drawings and need no description. The tile 14 with a dividing wall 15 and in and outlets 16 and 17 respectively for passing a liquid or other cooling medium through is set up at suitable intervals and bears inclined side walls. By means of this it supports a longitudinal arch in the side wall of the furnace. The tile 10 runs all along the furnace and is cooled in a similar way. (1,051,634, Jan. 28, 1913.)

Process of Improving the Quality of Malleable Iron and Steel.—The late OTTO THALNER, formerly with Bismarckhütte, in Germany, and later with Electro Stahl, in Reinscheid, worked out shortly before his untimely death a new process for refining steel in an electric furnace on acid hearth. The patent claims that the steel treated according to the process described has a peculiar crystalline grain very similar to, or substantially identical with, the grain which has always been observed in crucible steel, and which apparently gives to such steel its great tenacity. The process may be operated in a hearth-furnace and more particularly in an electric arc furnace, on acid or basic hearth, the heat being furnished by gas, electricity or in any other suitable manner. The feature of the process is the addition to the slag of a metallic oxide capable of giving oxygen to the bath of liquid iron and also to add carbon to such bath. The carbon is best used as carburite, which offers no difficulty in providing carbon both in and below the slag. The amount

of iron ore should not be so much as to cause red-shortening or blowholes in the metal, it will generally be found that between 1 and 2½ per cent of the weight of the liquid metal will be sufficient, while the weight of carbon to be added depends on the amount already in the metal and the finished carbon desired. As an example, it is mentioned that a bath of 5000 kg. desired to be finished at 1 per cent of carbon received from a 15 kg. carbon in the form of carburite, 30 to 35 per cent sand, 30 to 35 per cent lime, 5 to 10 per cent manganese ore to increase fusibility, and 25 to 30 per cent of iron ore. A correspondingly different slag would be made up for a basic hearth. In several chemical equations of an entirely hypothetical character the inventor gives one way of explanation of the reactions which are liable to occur during the refining action. (1,053,454, Feb. 18, 1913.)

Iron-Nickel-Copper Alloy.—Mr. G. H. CLAMER of Philadelphia, Pa., has obtained a patent on replacing part of the nickel of nickel steels with low nickel contents by varying amounts of copper. The latter element is known to raise the elasticity and tensile strength of such nickel steels without diminishing the ductility. Carbon is allowed to be present up to 0.5 per cent. Alloys claimed by this patent contain nickel up to 6 per cent and copper up to 2 per cent. A commercially profitable way of producing these alloys is the use of metal metal or an alloy of 68 per cent nickel, 2 per cent iron and 30 per cent copper. (1,050,342, Jan. 14, 1913.)

Method of Briquetting Flue-dust.—Mr. GEORGE L. COLLARD, of Sharon, Pa., has invented a new method of briquetting the flue dust from blast furnaces or other finely comminuted ore. He mixes limestone, sulphuric acid, and water with the dust until a pasty condition is reached, and molds the plastic mass by hand or any of the ordinary forms of briquetting apparatus. In practice if the dust contains below 0.5 per cent of lime, as is frequently the case, 3 to 4 per cent of crushed or powdered limestone are mixed with it. Sufficient water is then added to moisten the mass and render it suitable for molding. It is then treated with the sulphuric acid which causes the agglutination of the gas and thereby produces the good result of mixing the plastic mass. It keeps the dust in a coherent form until the temperature is raised sufficiently high to melt the metal. (1,047,174, Dec. 17, 1912.)

Process of Oxidizing Ferros to Ferric Solutions.—Messrs. ALEXANDER McKECHNIE and F. G. BEASLEY, of Birmingham, England, have found that the oxidation of ferrous sulphate and chloride solutions into the ferric salts can be rapidly and completely accomplished by subjecting same at a temperature exceeding 100 deg. C. to the action of air under a pressure of 10 atmospheres or upward. The oxidation proceeds so rapidly to completion that large volumes of ferric solutions can be cheaply produced under commercial conditions, whereas the oxidation by atmospheric oxygen or by air in open tanks under normal temperatures and atmospheric pressure proceeds so slowly that the process is practically useless. (1,047,826, Dec. 17, 1912.)

Synopsis of Recent Chemical and Metallurgical Literature.

Gold and Silver

Zinc Wafers for Precipitation of Cyanide Solution.—At the January meeting of the Chemical, Metallurgical and Mining Society of South Africa, Mr. JONAS MACARTHUR read a paper dealing with the use of zinc as a precipitant for cyanide solutions, and proposing the substitution of small sheets or wafers of that metal for the customary filament or shaving. The objections to the use of shavings are obvious: the cutting of the filament weakens the fibrous structure of the metal, and causes fractures which are plainly visible under the microscope. These fractures result in a great quantity of "short zinc" and zinc slime which cannot be separated mechanically from the valuable precipitate, necessitating acid treatment. Bullion may contain from 50 per cent to 100 per cent of such material, necessitating elaborate methods of refining. Another

objection to zinc shavings is the difficulty of packing them uniformly in the box, giving rise to spaces of varying resistance to the flow of solution, and consequent imperfect contact and precipitation.

Mr. MacArthur proposes to use wafers of sheet zinc, cut into sizes varying from 1 in. to 2 in. long and $\frac{1}{4}$ in. to $\frac{1}{2}$ in. wide. There is no virtue in any particular size, but oblong pieces are found to pack better in the box than square ones. The resistance of these pieces to the flow of solution is greater than that of shavings, so that boxes must be made with twice the customary fall, and may be only half as deep.

At the Caveira mine in Portugal these wafers have been in use since 1907, and the bullion precipitate is found to contain only about 3 per cent zinc and 12 per cent of other foreign matter. The usual acid treatment is dispensed with. Wafer zinc is used at another mine in Italy and one in Mexico, and the results are said to be excellent. The zinc is found to dissolve evenly, becoming thinner and thinner, until at the end of three or four weeks the wafers disappear altogether without having their structural strength impaired, and without leaving distinguishable debris. The wafers pack in the box in an irregular overlapping fashion, and as their edges are slightly burled or distorted by the cutting process, they do not lie flat on each other, but provide narrow channels for the passage of solution.

A Small Pachuca Agitator for Testing.—In the Colorado School of Mines Magazine for March, 1913, Mr. JOHN GROSS describes a small air agitator which he uses for testing purposes. It consists of a riveted pipe, 24 in. long and 6 in. in diameter, joined to a 7-in. glass funnel. The joint is made with a melted mixture of scrap rubber and sulphur, which is poured into the space between tube and funnel. This mixture hardens quickly, makes a tight joint, but is not brittle. Air is introduced through a piece of glass tubing fitted into the neck of the funnel by means of a rubber stopper, or any other convenient method of holding the tube in place. The lift-pipe is $\frac{3}{4}$ in. in diameter and extends from near the apex of the funnel to within a short distance of the top of the agitator. This lift-pipe is supported in place by suitable means at top and bottom. A settling chamber can be formed at the top of the agitator for the purpose of drawing off clear solution, by inserting a short cylinder, say 4 in. in height and of smaller diameter than the main cylinder, and rising 1 in. above the level of the pulp in the tank. By means of a siphon, clear solution can be decanted as desired.

With slime pulp not thicker than 2:1, the agitation is perfect, and no settling or accumulation occurs in the funnel; but with thicker pulps some thickening and settling occurs. With reground sand this settling does not occur, as the sand seems to have a scouring action which keeps the funnel clear of accumulations.

Compressed air can be obtained from an ordinary tank and pump such as is used for assaying with gasoline. When pumped to 30 lb. pressure the air will last for 20 minutes. The apparatus will serve for the agitation of 32 lb. of dry ore and the necessary solution.

Recovery of Gold by Volatilization.—In the December, 1912, monthly Journal of the Chamber of Mines of Western Australia, Mr. BEN HOWE describes "a process, the application of which, at any rate, is new to the metallurgy of gold." (?) It consists in roasting the ore with salt, volatilizing the gold as chloride, dissolving the latter in a water spray and recovering the gold in a filter press. He states that the gold is suspended, "as a black powder" in the water and readily recoverable in the press. Salt is added in quantities varying from 1 to 4 per cent, and the ore is crushed to different degrees of fineness; the finer the ore the quicker the volatilization. A rotary furnace is used, the temperature being maintained at about 1000 deg. C. A higher temperature sinters the ore, and a lower one does not effect volatilization. Laboratory experiments can be made by mixing ore with salt and subjecting the mixture to muffle-heat. The percentage of volatilization is said to be usually over 90 per cent. This process is attracting attention in

Australia on account of its experimental application to refractory ores from the Gwalia Consolidated mines in the East Murchison gold district.

Copper

Notes on Smelting Practice at the Copper Queen Smelter.

—In a paper on the Copper Queen mines and works, Douglas, Arizona, collaborated by members of the technical staff of the company, the portion devoted to the reduction works is contributed by Mr. GEORGE B. LEE. The entire paper is published in Bulletin No. 101, Inst. Min. & Met.

The original plant was erected in 1902, and consisted of five blast furnaces and four converters; this was doubled in 1906. The furnaces and converters are arranged in parallel lines on opposite sides of a 60-ft. craneway. The entire plant is on a nearly level site, there being a slope of about $\frac{1}{4}$ per cent from the receiving end to the furnaces. This makes it possible to run trains by easy grades from the ore pits to the charging floor, the distance being about 2000 ft.

The system of bedding ores, which is so common in lead smelters, has not been customary in copper works, where the ores have usually been classified in separate bins from which the components of the smelting mixture were drawn. The bedding system is used at the Copper Queen smelter, all ores being bedded to form a smelting mixture, while fluxes and fuel are kept in separate bins and added to the charges in transit from the ore pits to the furnaces. The ore is measured, but the fuel and fluxes are weighed.

Owing to changes in the ore, causing a reduction in grade of matte from 45 per cent copper to 30 or 35 per cent, and the increase in quantity of fine ore not suited to blast furnace operation, it was necessary to make some changes in the plant. Accordingly, six 18-ft. McDougal roasters and two 91 ft. by 19½ ft. reverberatory furnaces were added. Changes have been made also in the converter practice, substituting basic lined for acid lined converters. The lining of the present converter plant is preliminary only to an entirely new converter plant which will consist of vertical converters, 12 ft. diameter.

The subject of dust losses has been investigated, with the result that the new flues for the calcining and reverberatory furnaces are equipped with wire screens to cause the settling of fine dust. The original experiments to determine the extent of dust loss were made by passing a portion of the furnace gas through a set of closely woven bags. The smoke samples averaged 18,000 lb. each, and the per cent of dust recovered varied from 0.06 per cent to 0.16 per cent, the larger amount corresponding to the larger number of furnaces in operation. The dust contained about 9 per cent copper, 8 per cent lead and 5 per cent zinc. By further experiments it was determined that this dust would settle in flues if the velocity of the gas was reduced to 150 ft. per minute, while by the introduction of wire screens at 3-ft. intervals in the flues, the dust would settle equally well if the velocity were twice as great. The new dust chambers are of novel design, having a steel frame with hollow tile for floor, sides and roof. The latter is suspended from trusses exterior to the chamber. Similar experiments conducted on gas from the converters resulted in the recovery of from 0.015 per cent to 0.035 per cent dust, assaying half as much in copper, but twice as much in lead and zinc as the furnace dust.

As the result of a long series of experiments conducted with a view of devising some suitable way of mixing fine dust with converter slag for subsequent smelting in the blast furnace, the following plan was adopted. The mixing device is a truncated cone set with its axis horizontal. It is mounted on rollers after the manner of a barrel converter, and is revolved at the rate of 5 r.p.m. by a chain and sprocket. Molten converter slag and fine dust are introduced into this revolving cone at its small end; the slag being poured from a ladle and the dust delivered by pipe from a storage tank. The effect is to form a porous, lumpy material which is well suited to blast furnace smelting. The proportions of slag and dust are regulated by one man stationed so that he can see the discharged product which is a guide to the proportions used.

Notes on Copper Smelting in Russia.—The copper smelting works of the Société Minière de Bogoslovsk, Perm, Russia, has been in operation intermittently for the last 150 years, but it is only of late years that modern methods have been employed. A description of present operations is given by Mr. RICHARD DAVEY, in *Bulletin* No. 101, Inst. Min. & Met. The company was one of the first in the Eastern hemisphere to adopt the bessemerizing process, the plant dating back to 1885. The ores consist of chalcocite, chalcocite, pyrrhotite, cuprite, malachite and chrysocolla, with a gangue locally known as augito-garnet, with some calcite and a little free silica.

The principal features of the works are sinter-roasting of fine ore and flue dust in pots, granulation of slag, and the concentration of the gold and silver in the converters. The last operation is performed as follows: Three successive charges of matte are made to a converter, the charge being blown to the slagging point after each addition of matte. After the slag is removed from the third charge, the converter contains white metal assaying about 65 per cent copper. This is then blown until the rods used for punching the tuyeres show signs of metallic copper. The converter is then quickly tilted and the white metal run into a ladle and transferred to another converter to be blown to blister for ingot copper. The copper which remains in the first converter is found to contain practically the whole of the gold and most of the silver contained in the original matte, and this is cast into anodes for electrolytic separation.

The blast furnace makes a matte assaying from 30 per cent to 40 per cent copper, and the slags average 0.28 per cent copper. An analysis of the slag shows, in round numbers, 30 per cent silica, 12 per cent alumina, 34 per cent ferrous oxide, 0.3 per cent sulphur, 13 per cent lime and 1.5 per cent magnesia. The sulphur on the charge is 10 per cent, and the quantity of coke used amounts to 7 per cent of the gross charge. The converter slag which is not required for fluxing purposes is added to the furnace hearth in such a manner that it mixes with the flow of slag and matte from the furnace.

Transformation Point Apparatus

We have just received from the Leeds & Northrup Company a copy of their bulletin describing a new and interesting line of apparatus for the location of the critical points of iron and steel. This bulletin outlines two sets of apparatus, both

placed in immediate contact with it. The material of this metallic body, or sample holder, as it is termed in the bulletin is so chosen that throughout the range wherein lie the critical points of iron and steel, the sample holder has no such changes.

Hence the sample and sample holder will heat at the same rate and remain sensibly equal in temperature until the sample undergoes a change involving the absorption or evolution of

heat. At this time the temperature difference between the sample and sample holder previously approximately zero, undergoes a sudden change. This change, even in low carbon steels, is definite and great enough to be readily seen.

The two main advantages of this method are patent. In the first place, fluctuations in the rate of heating affect both the sample and holder practically simultaneously and are, therefore, of slight effect. It will be remembered that the more commonly applied method of plotting temperature against time can

FIG. 2. — TRANSFORMATION POINT INDICATOR

only be used with satisfaction to determine cooling curves on account of the effect of fluctuations in furnace. Then, in the second place, the temperature—temperature difference method has the decided advantage of utilizing a quantity (the heat of transformation) whose actual magnitude is small to cause a large percentage change in a second quantity (the temperature difference) which is being subjected to a series of measurements.

To illustrate this last point, suppose a steel to be of such composition as to liberate heat sufficient to change its temperature 2 deg. F., as in cooling it passes 1435. To note by the time-temperature method this, the reading and plotting arrangements must be capable of showing a change of two parts in 1435. On the other hand by the difference method even though the sample and its holder differed initially by as much as 5 deg., a change of 2 deg. would be a change of two parts in five or about 40 per cent.

We reproduce in Fig. 1 heating and cooling curves taken from a series of steels ranging from pure iron to 0.6 carbon steel. The left-hand curve of each pair is the heating curve and the right-hand the cooling curve.

The steel sample should be about 1 in. long by $\frac{3}{4}$ in. in diameter. Where it is required, the holder may be arranged for flat stock.

The temperature and temperature difference measurements are made with thermocouples. The temperature measuring couple is read with a simple potentiometer and the temperature difference is read with a reflecting galvanometer. In one equipment the Leeds & Northrup potentiometer indicator is used and the readings which are taken practically simultaneously from the potentiometer and from the reflecting galvanometer are afterwards plotted in form of curves.

With the transformation point indicator, an illustration of which is shown in Fig. 2, the observer draws the heating and cooling curve while the process is going on, without taking any readings. In this instrument cross-section paper is wound on a drum which also has wound upon it the slide wire of the temperature measuring potentiometer. The reflecting gal-

FIG. 1.—HEATING AND COOLING CURVES TAKEN FOR A SERIES OF STEELS WITH TRANSFORMATION POINT APPARATUS

fundamentally the same, but externally very different. We give herewith a reproduction of a series of typical curves taken from this apparatus.

In the curves plotted with this apparatus, the temperature of the sample as it heats and cools is used as one ordinate while the other ordinate is the corresponding temperature difference which exists between the iron or steel and a metallic body

vanometer of a difference couple circuit throws its beam upon a movable glass scale which also carries the pen which draws the record. As this galvanometer deflects, the glass scale is moved to keep up with the deflection, thus drawing the pen across the paper.

The galvanometer of the potentiometer circuit is also of the reflecting type and throws its beam upon a fixed scale. This circuit is held at a balance by turning the potentiometer drum thus drawing the line along the length of the paper. The resultant is of form similar to the curves shown herewith. Both motions are obtained by the rotation of shafts. Thus, at the completion of the test, the observer removes from the drum a finished transformation curve of the steel under test; he has drawn this curve by the simple process of turning two shafts in such a way as to maintain two spots of light on their respective scales. The manufacturers, the Leeds & Northrup Company, state that they have examined many varieties of carbon and alloy steels and that they have yet to find a steel which will not yield definite results on this apparatus.

Recording Differential Pressure Gauges

A comprehensive new line of recording differential pressure gauges has been developed by the Bristol company, of Waterbury, Conn. Some of these recorders have been in successful service continuously since the preliminary models were first sent out in 1908, and the design and construction of the line of these instruments now being placed on the market is based on results obtained in actual service during the last four years. These recording differential pressure gauges are designed for use in connection with venturi meters, Pitot tubes, orifices, combinations of orifices and Pitot tubes, etc., and thereby to record velocities and volumes of air, gas, steam, water and other liquids flowing through mains and pipes. These recorders may also be used to advantage for recording differences and variations of liquid level in steam boilers, pressure tanks, filter beds, process kettles, etc.

Important patents dated September 12, 1911, and September 17, 1912, have been issued to Prof. Wm. H. Bristol, president and founder of the Bristol company, covering novel features resulting from his pioneer work in developing differential recorders in addition to the other numerous lines of recorders which he has originated during the twenty four years which have elapsed since his first patent was allowed on a recording pressure gauge.

The fundamental principle employed in the construction of this differential pressure gauge is that one pressure is applied to the inside of the operating tube while the other is applied to the outside of the same pressure tube within a closed casing. In order to record the movement of the pressure tube it becomes necessary to transmit its motion to the outside of the pressure tube casing

FIG. 1.—RECORDING DIFFERENTIAL PRESSURE GAUGE.

As the differential pressure to be recorded is usually small as compared with the static pressure, the operative force is correspondingly small, and it is quite evident that it will be impractical to use a stuffing-box around a shaft passing through a pressure casing on account of the friction which would be produced. To avoid the use of a stuffing-box a unique frictionless

FIG. 2.—INTERIOR OF HELICAL PRESSURE TUBE TYPE OF RECORDING DIFFERENTIAL PRESSURE GAUGE

sealing device is employed as described in detail below.

Fig. 1 shows the exterior of one type of these recorders. Figs. 2 and 3 show part of the interior construction of the spring tube type differential recorder. In Fig. 2 pressure tube 15 is of the hollow helical type used with great success for many years in Bristol recording pressure and vacuum gauges. One of the pressures, the difference of which is to be recorded, is applied to the interior of this tube through the pipe 24 and the other pressure is applied to the exterior of this tube through the pipe 25. It will be noted that the pressure tube 15 is entirely enclosed in the pressure-tight casing 22. The movement of the pressure tube will be in proportion to the difference between these two pressures, and this motion is transmitted to the recording pen arm 12 (outside of the pressure casing) by means of small shaft 26 through the long tubular sleeve 27. The capillary action of the oil or liquid between the sleeve and shaft makes this patented joint both frictionless and pressure-tight.

In Fig. 3, 22 is the pressure-tight casing enclosing the diaphragm pressure tube 14, and in a similar way one pressure communicates with the interior and the other pressure with the exterior of this tube, and its motion is transmitted by means of the rotating shaft through the sleeve 21 to the recording pen arm 12. The length of this sleeve is many times the diameter of the shaft passing through it, differentiating it from an ordinary bearing.

This patented device permits of the recording of extremely small differences between the pressure existing respectively inside and outside of the pressure tube. It has been found that the simple frictionless sealing sleeve through which the pen arm shaft passes does not produce appreciable resistance to the rotation of the shaft, and at the same time capillary attraction and adhesion prevent leakage of even high pressures from the pressure casing.

FIG. 3.—INTERIOR OF DIAPHRAGM PRESSURE TUBE TYPE OF RECORDING DIFFERENTIAL PRESSURE GAUGE

In Fig. 4 diaphragm tube 8 is shown in the pressure chamber of the casing 11 directly connected to one end of the rotating shaft passing through the patented pressure seal, and having its other end directly connected to the recording pen arm 9.

This diagram also shows a set of interlocking valves 17, 18 and 23, which constitute a device for adapting recording differential pressure gauges to practical operating conditions. Cross-valve 22 is shown in an open position connecting the two pressure pipes. Valves 17 and 18 in the pressure pipes are shown closed. Both of these valves 17 and 18 can be opened allowing the static pressure from either pipe to be applied simultaneously to the inside and the outside of the pressure tube of actuating mechanism. The interlocking member 21 can then be turned through an angle of 90 deg., thus making it possible to close valve 22 which completes the connections so that the instrument will record the difference of the two pressures.

Fig. 5 shows a patented safety device consisting of a U-shaped tube 30, partly filled with a suitable liquid such as mercury or water, this tube having enlargements 33 and 34, each having sufficient volume to accommodate the quantity of liquid contained in the U-shaped tube. The length of the U tube varies with the range of the gauge so that the greatest possible head of the liquid contained in the U tube corresponds with the total range of differential pressure that the gauge is designed to record. Should the full static pressure by accident be admitted to either side of the differential gauge, the liquid contained in the safety U tube would instantly be forced up into one of the enlargements, thus allowing the static pressure to be applied simultaneously to both inside and outside of the pressure tube and protecting it from being destroyed. There is a great need for these instruments in many different industries and the field of usefulness for these is rapidly growing. Further information may be obtained from the manufacturers.

Centrifugal Separation

By Leslie Griscom

The use of centrifugal apparatus in removing liquid from solids and in separating liquids of different densities has a continually widening application. In the textile and sugar industries they have been in very general use for many years. Of more recent application has been the milk-and-cream separator, the medical centrifuge, and the Babcock milk tester. To illustrate the wide scope of the application of the centrifugal machine we will note a few of the materials on which they are used: General laundry work, yarns, piece goods (in rolls), felt boots, rugs, rubber, sugar, hides, curled hair, various kinds of salts, milk, printers' ink, and in bacteriological work, for concentrating germs, crystals, etc., for observation under the microscope.

A form of centrifugal has also been used for extracting honey from the comb, leaving the comb intact, so that it can be filled a number of times by the bees. As a pound of beeswax is said to take several times as much of the energy of the bees as a pound of honey, the honey extractor has proved a great benefit to the bee industry. The amount of moisture left in the material by a centrifugal varies greatly with different types of materials. With certain kinds of chemical salts it will be as low as 2 per cent or 3 per cent, while with fabrics and hair it may reach 50 per cent to 100 per cent of the weight of the dried material, this residual moisture being held by capillary attraction. Possibly few realize the force developed in a centrifugal machine. If we take as an example a 40-in. centrifugal running at 1000 revolutions per minute, a 1 lb. weight at the periphery will exert a centrifugal force of

$$F = 0.000341 WRN^2 = 0.000341 \times 1 \frac{1}{2} \times 1,000,000 = 508 \text{ lb.}$$

in which

W = weight in pounds

R = radius in feet

N² = the square of the number of revolutions.

Taking the same example, if we have a wall of material in the basket 5 in. in thickness the centrifugal head will equal

$$\frac{V^2}{2g} - \frac{V_1^2}{2g} = \left(\frac{40\pi \times 1000}{60 \times 12} \right)^2 - \left(\frac{30\pi \times 1000}{60 \times 12} \right)^2 = 207.2 \text{ ft.}$$

For water this equals a pressure of $207.2 \times 0.433 = 89.7 \text{ lb. per sq. in. at the periphery.}$

The strain set up in the shell of the empty basket (not allowing for thickness of shell) under the above conditions would be $0.0000204 V^2 = 0.0000204 \left(\frac{40\pi \times 1000}{12} \right)^2 = 3224 \text{ lb. per sq. in. cross section of metal.}$

It is somewhat of a paradox that while a much larger proportion of the liquid can often be removed from chemicals than from fibrous materials the centrifugal machine has had a very general application in the textile trade, while its use for drying chemicals, coal, etc., appears to have been comparatively undeveloped. For this latter purpose a strong, well-designed and well-built machine is necessary to take care of the heavy loads. Further, it must be of a self-balanced type, with bearings well protected, and where acid materials are operated upon the basket, etc., must be constructed of material that will resist corrosion. The machine should be constructed to discharge the material through the bottom of the basket to facilitate emptying. It should preferably be of an under-driven type to give free access to the top of basket. A direct connected motor makes a very convenient drive, doing away with belts and shafting. With the impregnated windings now furnished the motors are able to withstand the corrosive vapors to a remarkable extent. Where there is much explosive vapor a steam engine can be used.

A centrifugal of this type, built by Schaum & Uhlinger, Inc., Second Street and Glenwood Avenue, Philadelphia, has been in successful operation for some years, in the drying of ammonium sulphate and for other purposes.

FIG. 4.—CONNECTIONS FOR DIAPHRAGM TYPE RECORDING DIFFERENTIAL PRESSURE GAUGE

FIG. 5.—PATENT SAFETY DEVICE FOR USE WITH RECORDING DIFFERENTIAL PRESSURE GAUGE

These machines are substantially built of best material, and are being made to jigs and templates so the parts are interchangeable. The axle steel shafts are ground to gauge. Ample ball thrust bearings are provided which run in a bath of oil. Baskets are furnished either of steel or of material to resist corrosion. Curbs are made of heavy steel plates and lined when necessary to prevent corrosion. These machines are furnished for either belt drive or direct connected to motor through a flexible coupling. They also build a steam engine specially adapted to the operation of machines of this type.

Being under-driven the top of the machine is unobstructed, facilitating the charging and emptying of the basket. On account of the method of construction, and the heavy curb and base, these machines are comparatively free from causing vibrations in the buildings. Where desired, baskets having sloping

which have made possible the recovery of such waste products as wool grease at an actual profit.

We reserve a more detailed description of the equipment of the new Lummus industrial laboratory for a future issue.

"Semi-Producer" Furnaces

The recent rapid increase in the price of oil as fuel has brought various other processes prominently to the front, especially the use of powdered coal and the use of producer gas.

The W. S. Rockwell Company of New York City, has worked out an interesting solution of some difficulties experienced in the use of producer gas. Hot producer gas for average heavy work usually implies large, expensive flues, which soon become tar and soot clogged, and, in any case, entail the loss of a considerable portion of the sensible heat of the gas and take up a large amount of room. Cold producer gas means that moderate temperatures only are obtainable unless regeneration or elaborate recuperation is resorted to, since all the sensible heat of the gas has been lost, a portion of the volatile gases condensed to tar and there remains only a lean gas diluted with a large and worse than useless volume of nitrogen.

The solution of the W. S. Rockwell Company is very simple; it is to combine the furnace and gas producer; thus making a small, simple, self-contained, easily handled, efficient unit, covering within itself the entire heating operation from coal pile to heated product—having all the advantages of a hot producer gas furnace without the disadvantages of a separate producer and expensive connecting flues.

In this type of furnace the generation and distribution of the hot gas to the material in the furnace is accomplished without the loss of any sensible heat, without the condensation and

consequent loss of any of the tarry gases and with little loss of heat by radiation.

On these principles they have developed a variety of furnaces covering many classes of work. At all stages of the development the fact that good heating conditions must not be sacrificed in order to use a cheap fuel was borne in mind and the result has been a line of furnaces which involve such essential principles of good and economical heating as under-firing, recuperation, down-draft and absolute control of temperature.

While it has been impossible, of course, to cover all sizes and types of furnaces by this combination of furnace and gas producer, yet the fields which have so far been developed for this combination by the W. S. Rockwell Company, cover annealing, hardening, tempering, carbonizing, enameling, and other miscellaneous operations.

Metals and Alloys Free from Carbon Produced by the Thermit Process is the title of a very attractive and well written pamphlet of 30 pages, issued by the Goldschmidt Thermit Company of New York City. It contains concise technical information on the properties and uses of the following metals and alloys: ferrotitanium, chromium, ferrochromium, manganese and manganese alloys, ferromolybdenum, and vanadium.

Titanium in Steel—a Money Saver is the title of a very instructive and profusely illustrated pamphlet of 48 pages, just issued by the Titanium Alloy Manufacturing Company of Niagara Falls, N. Y., on the uses and benefits of ferrocarbon-titanium as a dioxidizer and scavenger of steel for various purposes, including, of course, rail steel. Particularly attractive and instructive are a series of microphotographs and a table giving the results of mechanical tests of steel treated with titanium. The pamphlet contains also the specifications which have been carefully worked out by the Titanium Alloy Mfg. Company to govern the addition of ferrocarbon-titanium for all kinds of steels.

CENTRIFUGAL MACHINE

bottoms are provided to facilitate emptying. They also provide a removable top to curb to facilitate removing basket, and provide hand holes in curb to render gutter accessible where the nature of the material handled requires frequent cleansing.

A New Industrial Laboratory and Demonstration Plant

The firm of Mr. Walter E. Lummus, of Boston, Mass., well known by his work in distillation engineering, has erected quite an elaborate industrial laboratory or rather demonstration plant, equipped to operate all kinds of processes involving distillation and evaporation on a manufacturing scale and an outline of some of the interesting work which is being carried out now in this laboratory is worth giving.

They are now building and testing apparatus for coating and drying fabrics with plastic compounds and recovering the solvents; also a plant for producing turpentine and other products from wood; further apparatus for extracting rubber from rubber-producing vines and shrubs.

There is further in course of construction a large continuous still for concentrating wood alcohol with recuperative heater, with a capacity of 10,000 gallons a day.

Nearly all the products of this firm are large apparatus for operation on a commercial scale, but they have under construction several interesting experimental apparatus. Among them is a new outfit for demonstrating fractional distillation, being built for Columbia University, further sundry experimental apparatus to be used, chiefly in connection with wood chemical and solvent extraction problems. Among these experimental apparatus is an extracting and distilling outfit which will be used by an important tropical trading company to de-resinate and concentrate sample lots of rubber.

A recent interesting achievement of Mr. Lummus is the development of remarkable economies in the concentration of extracted products by stage diffusion or extraction without heat

Personal

Mr. E. A. Austin, manager of the Guggenheim interests in the Iditarod district, Alaska, was a recent visitor at Stanford University, California, from which institution he graduated in 1906.

Mr. Herman Bacharach, until recently located at 722 Lewis Block, Pittsburgh, Pa., has moved into larger quarters at 1009 Hartje Building. He has enlarged the number of his specialties in scientific and industrial instruments, which now include smoke and dust recorders, specific gravity meters for gas and liquid, carbon dioxide recorders and engine indicators with automatic efficiency reckoner, etc.

Mr. Charles W. Badgley has resigned his position as chemist in the research laboratory of the American Smelting & Refining Company, at Perth Amboy, N. J., and has accepted the position of chief chemist for the El Paso Smelting Works, El Paso, Texas.

Mr. George H. Benjamin, consulting engineer, expert in patent causes, and solicitor of patents, announces the removal of his offices on April 15, 1913, from 45 Broadway to 66 Broadway (Manhattan Life Building) New York City.

Mr. D. W. Buckby has been appointed superintendent of the Stewart mill at Wallace, Idaho. For some time past Mr. Buckby has been engaged in experimental work for the Federal Mining & Smelting Company, of Idaho.

Mr. J. Parke Channing, consulting engineer for the Miami Copper Company, recently inspected the company's property at Miami, Arizona.

Mr. E. C. Engelhardt has left Garfield, Utah, to accept the position of smelter superintendent with the Idaho Smelting & Mining Company, at Clayton, Custer County, Idaho.

Mr. Le Roy Gordon has been appointed manager of the New York office of the Nelson Valve Company and Yarnall-Waring Company, with offices at 30 Church Street, New York City. Mr. Irving N. Beeler has been appointed district sales manager for central New York with offices in the Bastable Building, Syracuse, N. Y.

Mr. Franklin Guitermann, technical director for the American Smelting & Refining Company, with headquarters in New York City, was in Denver in March on a periodical trip of inspection.

Mr. A. B. W. Hodges, who left British Columbia three years ago to assume general management of the Cerro de Pasco company in Peru, has finished his contract and will return to the United States.

Mr. D. C. Jackling, general manager for several copper companies in Utah, Arizona and New Mexico, will change his residence from Salt Lake City, Utah, to San Francisco, Cal.

Mr. J. G. Kirchen was recently re-elected a director of the Tonopah Merger Company, and will continue as general manager of the company's operations at Tonopah, Nev.

Mr. W. A. Kunkle has resigned as superintendent of the Ajax mill at Victor, Colo., and will engage in consulting practice in Denver, Colo.

Mr. William D. Leonard, superintendent for the Garfield Smelting Company, Garfield, Utah, was a recent visitor in Denver.

Mr. Edgar Rickard, manager of the *Mining Magazine*, London, has been making an extended visit in the United States.

Mr. Haller R. Robbins has been appointed assistant professor of metallurgy at the State College of Washington, Pullman, Washington, succeeding the late R. E. Sampson.

Mr. J. F. Thorn has resigned as general superintendent for the Goldfield Consolidated Mines Company, Goldfield, Nev., and will be succeeded by Mr. Albert Burch.

Mr. William Wraith, general manager of the International Smelting & Refining Company, Salt Lake City, recently inspected the new electrolytic lead refinery built by his company at East Chicago, Indiana.

Obituary

Dr. Frederic Schniewind, the widely known pioneer of the by-product coke oven industry in the United States, died on March 12 in New York City. He was born in Germany 52 years ago and a graduate of the University of Heidelberg, where he received the degree of Ph.D. He came to this country in 1889 and by introducing the Otto-Hoffman coke oven he became the founder of the by-product coke oven industry in this country. At the time of his death he was president of the German-American Coke & Gas Company and its subsidiaries, the United Coke & Gas Company and the Coke & Gas Construction Company.

Mr. George E. Gunn, who has been a prominent figure in Western mining and metallurgical circles for the past twenty years, died suddenly of heart disease in his apartments in Hotel Utah, Salt Lake City, Utah, on March 11, 1913. Mr. Gunn was fifty years old at the time of his death. He had been prominently connected with the development of Western porphyry copper mines, having had his attention directed to their possibilities while engaged as field engineer for the American Smelting & Refining Company. He also acted as general manager for the company which developed the large lode copper mines and erected a modern custom copper smelter in the Mason Valley district, Nevada. He was associated with Mr. William B. Thomson in the Gunn-Thomson company which originally developed the Inspiration copper property in Arizona, later sold to the Amalgamated interests. The same company is owner of the Magna copper mines in Arizona. Mr. Gunn was a wealthy bachelor, and member of several clubs in Salt Lake City, on the Western coast, and in the East.

Digest of Electrochemical U. S. Patents

Prior to 1903.

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

ORE TREATMENT (Continued).

694,349, March 4, 1902, Henry R. Cassel, of New York, N. Y. Relates to a process for recovering gold from refractory ores, such as sulphides, tellurides, etc. Such ores require roasting to set the gold free; by the present process, it is stated that roasting is avoided. The ore is finely pulverized and mixed with water containing about 3 per cent of salt to form a pulp. This pulp is agitated in an open tank (described in patent 694,350), having a lining of carbon connected as one electrode and carbon-coated stirrers connected as the other; the polarity of the electrodes being reversed at will. The current forms hypochlorites and oxychlorides, which oxidize the sulphur, tellurium, etc., setting free the gold. The gold and oxides of alkaline earth metals are precipitated upon the negative electrode as a black powder, from which it is scoured off by the pulp. The gold precipitate is dissolved by cyanide of potassium, which is finally added, and stirring continued; the gold is recovered from the cyanide solution by the usual method.

694,350, March 4, 1902, Henry R. Cassel, of New York, N. Y. Relates to apparatus for carrying out the process in patent 694,349. Within a tank suitably coated with cement, to prevent leakage, and lined with carbon blocks electrically connected as an electrode, there rotates an insulated metal shaft carrying radially projecting stirring-blades of metal and covered with carbon plates. The shaft and stirrers are electrically connected as the other electrode, and both connected to a suitable source of alternating current; or preferably to a continuous current which is periodically reversed. In operation, the ore, mixed with water containing enough salt to render it conductive, is charged into the vat while the stirrers are rotating. After the gold is set free from the ore, a solvent such as potassium cyanide is added to dissolve it, from which it may be recovered as usual.

698,202, April 22, 1902, Edward D. Kendall, of New York, N. Y.

Relates to a process for separating metals from solutions, such as gold from cyanide. Within a suitable tank containing a porous cup is a mass of carbon presenting a large surface, and connected electrically to a source of current at about 15 volts. Within the porous cup is preferably a solution of caustic soda or potash, and a carbon plate connected as the other electrode. The mass of carbon is first connected as cathode and a gold-bearing cyanide solution allowed to flow continuously there-through, the gold being electrolytically deposited upon the carbon. The cyanogen liberated at the anode is absorbed by the caustic soda. When a considerable quantity of gold is deposited, the carbon plate is removed from the porous cup and a silvered copper plate inserted: the cyanide solution in contact with the mass of carbon is now replaced by a stronger cyanide solution and the electric current reversed, making the mass of carbon the anode and the silvered copper the cathode. The deposited gold, etc., is dissolved from the carbon and redeposited upon the silvered copper within the inner porous cup, from which it may be stripped from time to time. After the gold has been removed from the carbon, the strong cyanide solution is drawn off, the silvered copper plate replaced by the carbon plate, the electric current reversed, and the process of treating the gold-bearing cyanide solution repeated.

699,964, May 13, 1902, Frederic H. Long, of Chicago, Ill., assignor to Ross J. Beatty, trustee, of Muncie, Ind.

Relates to an improvement on his earlier patent 650,646. In operating the apparatus described in that patent it was discovered that gases were liberated in the cathode compartment and collected under the diaphragm, thereby increasing the electrical resistance. In the present patent a vent-pipe projects into the cathode compartment to carry off the gases, and also provides means to condense and collect any vapors of acid, etc., entrained by the gases.

700,563, May 20, 1902, Samuel S. Sadtler, of Philadelphia, Pa. Relates to the extraction of zinc from ores, etc., and from zinc scrap. The ore is pulverized to about 200 mesh and treated with sodium hydrate and hypochlorite of soda in a suitable tank; this dissolves the ore forming zincate of soda and separating sulphur, as follows:

The solution is allowed to settle and the clear liquid run into the cathode compartment of an electrolytic cell, the zinc being deposited upon a suitable cathode. The resulting sodium hydroxide is run into the anode compartment where it may be converted to the hypochlorite by the addition of a suitable quantity of sodium chloride and then used to treat a fresh quantity of zinc sulphide. Zinc scrap, tin scrap, zinc crusts, etc., may also be treated by this process.

700,941, May 27, 1902, Nathaniel Shepard Keith, of Arlington, N. J.

Relates to a process for electrodepositing copper from its solutions, preferably the sulphate. The electrodepositing cells are connected in series both electrically and hydraulically; the electrodes are so proportioned that there is a higher current density per square foot of electrode in the cells at the beginning of the series, where the electrolyte enters than at the end where it leaves. The current density decreases as the copper content decreases, thereby producing a uniform reguline deposit of copper in each cell. The exhausted electrolyte is used to treat a fresh supply of ore and produce more electrolyte.

702,153, June 10, 1902, Jarig Philippus van der Ploeg, of the Hague, Netherlands.

Relates to the extraction of antimony from its ores, etc., and consists in mixing the finely powdered antimony ore with a suitable quantity of quicklime and a monosulphide or polysulphide of calcium or magnesium according to the quantity of antimony present. When water is subsequently added, soluble double sulphides of antimony and calcium or magnesium are formed, whereby all the antimony may be removed from the ore. The solution containing the antimony sulphide is electrolyzed, or may be treated with an acid, such as hydrochloric acid, to precipitate the antimony sulphide.

Book Reviews

The South African Mining Directory. A monthly handbook. Published by the South African Mining Directory, Ltd., 119 Exploration Bldg., Johannesburg, Transvaal, South Africa. 208 pages, 5¼ x 8; price, £2 10s.

This is a new publication, issued for the first time in November, 1912. Among mining directories it should hold a premier position for accuracy by reason of its frequent publication.

The customary objection to all such directories is that they soon become out of date on account of the changes in the personnel of the business and technical staff of the companies. As this directory is to be issued monthly it will be free from that objection. The first number is quite complete, giving data on the organization of the companies, and a roster of the principal officials. All the mining industries in South Africa and Rhodesia are covered, comprising gold, copper, tin, coal and diamond mines. Statistics on the annual purchases of South African mines, and an alphabetical index of mine officials, complete the volume.

* * *

Refractories and Furnaces. By F. T. Havard, E. M. 6 x 9 in. (15 x 23 cm.), 356 pages, 123 illustrations; price \$4.00. New York: McGraw-Hill Book Company.

The author was in practical work as superintendent of smelting furnaces, and some notes on furnace linings made at that time served as the nucleus of this book. By collecting and adding to these the scattered data on refractory materials, heat conductivity of materials, and heat losses by radiation and convection, the work has been completed.

It discusses refractories primarily and furnace construction incidentally.

The treatment is highly scientific yet intensely practical throughout, and it is just the kind of book which was needed, both for the university and the works. We advise everyone having anything to do, or to work out, in this line, to get the book, and to get it quickly, for while a better book may be written in the future, there is no work at present in print which covers the subject so satisfactorily.

* * *

Electroplating. A Treatise on the Electrodeposition of Metals, including Metal-coloring and Bronzing. By Wm. R. Barclay and Cecil H. Hainsworth. 12mo. (12 x 18 cm.), 399 pages, 62 illustrations. Price \$2.10. London: Edward Arnold. New York: Longmans, Green & Company.

This is primarily a handbook for the practical electroplater, to help him drop rule-of-thumb and to work scientifically. The book is an amplification of lectures delivered at the University of Sheffield by Mr. Barclay. While giving data in ounces Troy and avoirdupois, yet the book lays its main emphasis on using the metric system, and thus tries to lead the electroplaters to the simple, modern decimal system.

The writers not only describe present electroplating methods, but they look ahead and foresee advances in the art. For example, speaking of lead, tin, and antimony, they say that "at the present moment, and writing from an electroplating point of view only, the three metals dealt with in this chapter * * * are of comparatively little interest for the practical worker. It is quite possible and even probable, however, that the immediate future will witness an increase of the commercial possibilities of electroplating with these metals, and some little space should therefore be devoted to an outline of the principal methods of their deposition." Very well said; a book written in such a spirit cannot fail to be valuable and inspiring.

The April meeting of the American Electrochemical Society will show how accurate was the foresight, at least as regards "lead." The field of the electroplater is rapidly widening, as the point of view and education of the electroplater are broadening.

The Coming Denver Meeting of the American Electrochemical Society

The next meeting of the American Electrochemical Society will be held in September in Denver, Col. During the first eleven years of its life the American Electrochemical Society has become truly international in membership, activity and prestige. The coming years, with the Denver meeting this fall, the proposed meeting in Birmingham, Ala., in the fall of 1914, and a San Francisco meeting in 1915, will give an opportunity to broaden and strengthen the national scope of the society.

In view of such a nation-wide activity the question may be asked: What can electrochemistry do for the country? With respect to the Denver meeting the question becomes more specific: What can electrochemistry do for Western metallurgy? It is natural that the discussion of just this question will mark the keynote of the Denver meeting, a symposium of papers being arranged discussing broadly the potentialities of the applications of electrochemical methods and principles of physical chemistry in Western metallurgy.

If the mountain does not come to the prophet, the prophet has to go to the mountain, and no particular power of prophecy is needed to say that the meeting will be interesting. Electrochemists are born good mixers. Electrochemistry is a borderland of sciences and a borderland of industries. In our age of specialization the scientist and the engineer each uses his own jargon, and so does the physicist, the chemist, the metallurgist and all the otherists of man-made professional distinction, and in this one respect at least modern methods of progress often resemble now the building of the tower of Babel that those who work on the promotion of civilization, each in his own way, no longer understand each other's language.

To remove such man-made gulfs or at least to bridge them firmly, this has been one and perhaps the most glorious function of the American Electrochemical Society. The society has brought together engineers and scientists, to look at each other no longer with distrust, but with mutual respect. Those of its meetings which were devoted especially to particular human mixing reactions, like the Pittsburgh meeting and the recent Atlantic City meeting, have been eminently successful. The Denver meeting should become another milestone in the career of this society.

Electrochemistry and the Electroplating Industry

The symposium on electrodeposition of metals at the Atlantic City meeting of the American Electrochemical Society will add considerably to that Society's already well-deserved reputation as a meeting ground on which men interested respectively in the practical and theoretical aspects of industrial science come together on a basis of

mutual assistance and respect. Such mutual attitude is unfortunately not too commonly met with in the field of applied chemistry, possibly owing in part to the patronizing attitude which too many well-meaning official or academic chemists adopt towards those engaged in industries of which electroplating is typical, in which full advantage is decidedly *not* taken of current scientific knowledge.

The imaginative common sense of the retiring President of the American Electrochemical Society, Professor W. Lash Miller, led him to try the experiment of bringing electrochemists and electroplaters into personal contact and mixing them vigorously in the hope that a solution—or at least an emulsion—might result. If the immediate outcome of the experiment was to demonstrate the surprisingly high values of the surface tensions involved, this merely indicated the desirability of continuing experiments with the view of reducing these. The appointment of a committee to maintain coöperation between the Electrochemical Society and the Electroplaters' Association was the outcome with (appropriately enough) that master of emulsification, Professor Wilder D. Bancroft, at its head.

This seems to us a decided step in the right direction. It is often too readily assumed, when the application of current scientific knowledge is absent from such an industry, that this is because the industrial men do not want it, and that such application is an easy matter. Both these ideas received a violent refutation at the Atlantic City symposium. The interest and enthusiasm of the attending electroplaters, and their obvious desire to absorb anything electrochemistry could give them were remarkable; if they don't get much benefit from electrochemical science it isn't at any rate because they don't want to.

Even more notable was the obvious gulf between the two parties to the discussion. Not only did they not, as both admitted, "speak the same language"; it was hardly possible for them to come into contact on any point. This gulf cannot be airily disposed of by telling the electroplaters they are on the wrong side; it has to be bridged, and to this end the best joint efforts of both parties on the committee may well be directed. The strongest promise of success in this aim is offered by the spirit of coöperation in which the two organizations have approached the matter.

The first step in the direction of improvement is, however, one which those electroplaters who have not yet taken it can best learn from those who have, viz., the rigid application of method and the systematization of all procedures. We are acquainted with electroplating plants in which methodical supervision and close record-keeping have led by themselves to extraordinary improvements in working. It need hardly be pointed out that this is nothing more or less than the application of scientific method, and that without it an electroplater will look in vain for assistance from scientific knowledge.

Moving Pictures for Industrial Purposes

The photograph has long been recognized as a valuable adjunct to oral and written description. In many cases the simple projection of a lantern slide, or the printed reproduction of a photograph, conveys quickly and definitely an idea which might require a long, involved and less

satisfactory verbal explanation. The general adoption of this method in educational and commercial work proves its value. More recently the development of the moving picture has called attention to possibilities in this line which have only begun to be realized. In the field of metallurgy there is an opportunity that should appeal to both educational and commercial institutions, to use moving pictures for more clearly presenting and explaining the operation of many machines which work continuously or in a cycle of intermittent steps.

It is customary in engineering schools for the instructors to illustrate some lectures by means of stereopticon views. The method is excellent, but might be vastly improved by the use of moving pictures. Consider the number of metallurgical operations that could well be illustrated by the latter method: Crushing and grinding, classification of sand and slime, sizing by various forms of screens and the screenless sizer, sinter roasting, concentrating, vacuum filtration by the movable leaf or revolving drum types of filters, handling and conveying materials, charging and discharging blast and retort furnaces by hand or machinery, bessemer converting, dressing amalgamating plates, and so on. The operation of an entire metallurgical plant could be presented on one film, taking the different steps in the process in proper sequence, giving in effect a trip of inspection through the plant.

For the manufacturer of metallurgical machinery, the moving picture may be an adjunct in advertising, promoting and selling. Recently one manufacturer resorted to this method with good effect. His machine was new and little known or understood; it embodied some principles that were novel, and its operation was not easily described; catalogs were inefficient in conveying an idea of its full value. A few hundred feet of film, however, showing the machine in operation, demonstrated quickly and convincingly the nature and scope of the machine and its method of operation. In such cases, simple photographs fail to convey the idea of operation, and leave too much to the imagination. The moving picture, on the other hand, gives the effect of an actual demonstration, and is far more effective than photographs or verbal description. In view of the widespread use of machines for projecting moving pictures, films can be shipped to any important point for demonstration.

Cleaning Filter Cloths.

The prevalent method of treating filter fabrics for the removal of incrustations and deposits of lime and other earthy salts, is with a solution of hydrochloric acid. The method has its disadvantages and is not wholly in favor; filter cloths suffer some deterioration under the action of the acid, and additional tanks may be required. In our issue for last month we noted a patented process for cleaning filter fabrics and screens by the use of a sand-blast. By this method the outer surface of the dried fabric is subjected to the action of the abradant. If the size and hardness of the material used in the blast is carefully selected, and the pressure of the blast properly regulated, it is claimed that the fabric suffers less deterioration than when treated with acid, and that the removal of the incrustation is very effective.

The use of the sand-blast for this purpose is not entirely new, especially in other countries. We believe the idea was first applied in Kalgoorlie, Western Australia, in connection with filter pressing. A great deal of trouble was experienced there with calacorous deposits from the water, which was heavily loaded with salts. Incrustations formed on the plate-and-frame presses to such an extent that after breaking a press it was almost impossible to make tight joints between the members when setting the press up for another run. The deposit resisted removal by scraping or other means, and the sand-blast was called into use with good effect.

From Western Australia the practice spread into New Zealand, where it was used on filter fabrics with more or less success and satisfaction. From New Zealand the method was taken to South Africa. In the latter country the practice is in vogue at one or two mills with fair success. The sand is fed into an open conical hopper which forms a reservoir. A pipe for compressed air extends downward to a point near the apex of the cone, and from the latter point a flexible hose and nozzle conduct the blast to the filter fabric. In the United States the process is in use at the Golden Cycle mill.

Still another proposal for cleaning filters is the use of steam under about ten pounds pressure, assisted by a subsequent wash of hot water. This method has been very effective at one of the cyanide mills in the Black Hills of South Dakota, having been introduced there by Mr. F. C. Bowman. The filter is of the drum type. When the cloth needs cleaning, steam is forced through successive sections of the filter by means of the pipe ordinarily used to conduct compressed air to dislodge the cake. The effect of the steam is to immediately loosen and disintegrate the deposit of lime, after which it can easily be washed out by hot water, leaving the meshes of the cloth clean and free.

Rolled Steel and Cast Iron

It is interesting to note that common knowledge and such statistics as can be cited unite in testimony that the iron casting is decadent as compared with its vigorous rival in the ferrous material field, rolled steel. Continually one hears of new uses to which steel is put, and practically all these uses involve rolled steel. Metal furniture employs rolled steel, the automobile carries much rolled steel, a little forged steel and an occasional steel casting, but a negligible amount of cast iron. Sheet piling, concrete reinforcing bars, relatively new products, are of rolled steel. The cast-iron column is decadent in building construction, while the skeleton structure of rolled steel thrives amazingly. The cast-iron carwheel is losing ground to steel, though in this case the steel product is either a real forging or is rolled in a manner which does not place it within the category of the ordinary rolled-steel product. In the majority of forms of hardware rolled steel has long been replacing cast iron.

A few references like these are amply suggestive of the rapid march of rolled steel, and of the relative, if not absolute, decadence of the iron casting. Inasmuch as the total production of ferrous material, measured by the production of pig iron, which is a fair index despite the use of a moderate amount of old material, has been increasing

rapidly, doubling in a general way every decade, it requires close scrutiny to determine whether the decadence of the iron casting is absolute or merely relative to rolled steel. There have never been statistics of the production of iron castings, but the production of foundry iron should furnish a valuable clue, for the consumption of cast-iron scrap in the foundry cannot have increased very rapidly. The full statistics of pig-iron production by grades in 1912 are not yet available, but there are statistics which segregate Bessemer, basic and manganese bearing metals from other pig iron, and these show that the production of foundry, malleable, forge and miscellaneous grades was slightly less than 6,500,000 gross tons in 1912, whereas in both 1910 and 1909, the next best years in total pig-iron production, the output of these grades was about 6,750,000 tons. The total production, however, has been: 1909—25,795,471 tons; 1910—27,303,567 tons; 1912—29,727,137 tons. Here was a large increase in total pig iron, and a decrease in the foundry grades.

The statistics of the market seem to bear the same testimony. In the general revival in the iron and steel industry in 1912, rolled steel products advanced until they reached a certain level, early in October. Since then the level has been maintained, there being practically negligible advances and declines. Foundry pig iron, on the other hand, after reaching a high point in December, has steadily declined in price, and in the past month the declines have been particularly rapid. With quoted prices unchanged, the steel mills have month by month been realizing better prices on their shipments, as old and lower-priced contracts were worked out, while at the same time pig iron, which has certainly been subject to no adverse influence from the steel trade, has been declining.

It is one of the adages in the iron and steel trade that in case of a general improvement in the industry the foundry trade finds its improvement about six months later than the steel trade, lagging behind it by about this distance. Before this time, therefore, there should have been a very distinct improvement in the foundry trade, which one would naturally expect to find in its reflection in the market prices for pig iron.

It is sometimes suggested that the iron casting is yielding to the steel casting. As a generalization, this is altogether a misconception, though it is undoubtedly true in a few specific instances. One must compare totals to reach a proper conception. As long ago as in 1906 the production of steel castings amounted to 773,705 gross tons, while in that same year the production of forge pig (of which but a very small tonnage really reaches the puddling furnace), foundry iron and malleable iron, exceed 6,000,000 tons, and making allowance for the consumption of scrap the production of iron castings undoubtedly much exceeded this figure. Yet it is a fact that, with 1912 still to be reported upon, there has been no year in which the production of steel castings has reached a million tons, showing that the tonnage gain since 1906 has been altogether insignificant. Thus the steel casting has not replaced the iron casting to any appreciable extent. The statistics for 1912 when presented will undoubtedly show that in point of percentage the steel ingot has grown much more since 1906 than the steel casting.

Readers' Views and Comments

"Thermistry" and the "Thermist"

To the Editor of Metallurgical and Chemical Engineering:

Sir:—What shall we call the man who has charge of the heat treatment of steel or for that matter of any metal or alloy? He is hardly a metallurgist or metallurgical engineer although those terms are sometimes applied. Neither is he a chemist, although the chemist often has charge of heat treatment; yet the man in charge of the latter may know very little chemistry.

Here then is a distinct position or grade which is becoming more and more important as we more fully understand the possibilities of this branch of metallography. Then why not call it by a distinct name?

Thermistry then, is the art and science of heat treatment and heat measurement and the practitioner would be a thermist. The name is descriptive, dignified, concise, and much less awkward than "metallurgist in charge of heat treatment" or "engineer in charge of heat treatment."

H. M. BOYLSTON.

Cambridge, Mass.

Volatilization Processes in the Metallurgy of Gold

To the Editor of Metallurgical and Chemical Engineering:

SIR:—On page 220 of the April, 1913, issue of METALLURGICAL AND CHEMICAL ENGINEERING, there appears a review of an article originally published in the monthly *Journal* of the Chamber of Mines of Western Australia regarding the recovery of gold by volatilization. In the original article the author, Mr. Ben Howe, states that his process merely takes advantage of a fact long known to metallurgists of the old chlorination school, viz., that when gold ores are roasted with salt the precious metal is volatilized in greater or less degree, according to the conditions of temperature, time and composition of the roasting mixture. By determining the proper conditions for the roast, Mr. Howe finds that he can volatilize the gold to such an extent as to constitute an efficient method of extraction. He further observes that this is "a process, the application of which, at any rate, is new to the metallurgy of gold."

It has been remarked that methods and machines that are old and well known to one generation or to one part of the world are rediscovered and revived by later investigators or in another section. The present instance is a case in point. About 1897 or 1898 Mr. Edwin C. Pohlé and Mr. Stuart Croasdale, then respectively chief assayer and chief chemist for the Globe Smelting & Refining Company, Denver, Col., devised and patented a process based on the same principle as that suggested by Mr. Howe. Mr. Pohlé was first led to investigate the volatilization of metals as a result of serious losses encountered in assaying high-grade silver ores from Aspen, Col. When an assay was made with the customary "salt cover" wide variations occurred in the results, which, however, were more uniform when no salt was used. The two gentlemen named then began a serious investigation of the subject, with the idea of using volatilization in the recovery of metals, particularly from refractory ores.

They found that gold, silver, lead, and copper could be almost completely volatilized from most ores. It was necessary to have in the ore some form of sulphide, in proper proportion to react with the added sodium chloride. The reaction liberated nascent chlorine which combined with the metals to form volatile chlorides. If the ore contained a high percentage of sulphide it was first partly roasted; if it contained none, or not enough, raw pyrite was added. The laboratory tests were simple so far as volatilization was concerned, but recovery was a different matter. The process was finally worked

in an experimental plant in Denver, and later a commercial plant was erected at Mayer, Ariz. The latter was never operated, as far as I am aware.

It may be surmised that the stumbling block to success was the recovery of the volatilized chlorides. As one metallurgist remarked, it was difficult to see the wisdom of converting the metals into a less tangible condition than that in which they already existed in order to attempt their recovery. Bags, sprays, solution towers, etc., were tried at the recovery end, but without success. The problem was never satisfactorily solved. The volatilization feature, however, was attractive in regard to refractory ores, for they usually yielded to the treatment.

There is one possible solution of the recovery problem which has occurred to me since the development of the Cottrell method of fume condensation by means of a high-potential electric discharge. The volatilized metal chlorides might be suitably condensed by the Cottrell process, forming a concentrate of mixed chlorides, which could then be separated by chemical means. In the absence of any information as to how the Australian metallurgist is to recover his chloride fumes, it will be interesting to await further developments. His process, however, certainly is not "new to the metallurgy of gold."

Denver, Col.

H. C. PARMELEE.

Simple Rules for Temperature Conversion

To the Editor of Metallurgical and Chemical Engineering:

Sir:—I am interested to read Dr. Hering's communication in your April issue (p. 176), on mental calculations from the Centigrade to Fahrenheit thermometer scales and vice versa. He omits, I think, one for which I claim no originality, but find convenient. It is not approximate, but exact.

In either case, whether Centigrade or Fahrenheit, add 40 to the reading, then if Fahrenheit take five-ninths and subtract 40, or if Centigrade take nine-fifths of the sum and subtract 40.

My attention was called to this by one of my students, and I find it a simple method.

D. H. CHILDS.

Technical High School,
Buffalo, N. Y.

* * *

To the Editor Metallurgical and Chemical Engineering:

Sir:—As many of your readers know, the conversion of daily temperatures in Centigrade degrees into Fahrenheit degrees is the bug-bear of Americans traveling in Europe, and who has not seen the letter published daily in the Paris edition of the New York *Herald* about the following effect?

"Dear Editor:

Can you furnish me with a simple rule for converting centigrade temperature into Fahrenheit?

"Most sincerely yours,

"YOUNG PHILADELPHIA LADY."

Your last number contained a gallant attempt at a solution of this perennial problem, signed oddly enough "Philadelphia," but alas it was not intended for use in these latitudes, and we hope and trust that the "Young Philadelphia Lady" may never experience, here or hereafter, the temperatures for which Dr. Hering gave his approximate but very convenient rules. No; for purposes of discussing the weather, the problem has not yet been solved, except by the time-honored expedient of memorizing a few fixed points, such, for example, as that 10° Centigrade is 50° Fahrenheit and every 10° Centigrade more or less is 18° Fahrenheit higher or lower than 50° Fahrenheit, every 5° Centigrade is 9° Fahrenheit, and every 1° Centigrade is 1.8° Fahrenheit. This simple mental exercise solves all the weather problems.

South Bethlehem, Pa.

JOS. W. RICHARDS.

Alumina from Clay by the Fluoride Process

To the Editor of Metallurgical and Chemical Engineering:

Sir:—I have been much interested in the symposium of papers on alumina in your March issue and would like to add something to the discussion.

When a mixture of aluminium fluoride and clay, in such proportions that atoms of silicon and fluorine are to each other as one to four, is heated to a red heat in the presence of water vapor, silicon fluoride passes off and alumina is left.

The only surprising thing about this is the completeness with which this occurs, and the small excess of fluorine needed to secure the complete elimination of silica. In a previous paper (Eighth International Congress of Applied Chemistry, Inorganic Section, Original Communications, Vol. II, p. 67, and Vol. XXV, p. 115), under the title "Action of Some Fluorine Compounds on Clay, Water, etc." I gave results of tests made on some of the details of the process of producing alumina from clay in the above manner. The resulting silicon fluoride reacts with steam or a water spray, the silica is separated by centrifugal action, and the gaseous hydrofluoric acid passes up through a tower filled with clay, over which a small stream of water is flowing. The acid solution from the tower is treated with excess of mildly calcined clay, precipitating the excess silica, much of the iron and titanium, and regenerating the aluminium fluoride.

Two important questions—after the one, "Will it work?"—are, first, the cost of the alumina, and second, the purity. And in that order, because two-thirds of the alumina comes from the calcination of the aluminium fluoride by the reaction

and that fluoride of aluminium can be made of good purity by proper neutralization with clay.

While no claim is made that metal for electrical conductors can be made by this process because small amounts of impurities so greatly affect the conductivity, yet the other uses are for which such metal cannot be properly recommended.

Further on the subject of purity, I find that half the titanium and more than half the iron of the mixture are volatilized with the silica in the calciner. As to costs the first point must be the recovery of the fluorine. From 80 per cent to 90 per cent has been recovered in the laboratory, and probably that figure will stand until some larger tests are made.

On the 80 per cent basis, calculations show a cost per ton, including the factors of labor, power, fuel, acid and fluorspar in the neighborhood of \$17. Appreciating the doubt that properly clouds all calculations based on laboratory tests, it is nevertheless interesting when those calculations give a low value.

We are now building a calcining and absorbing set to try this out on a larger scale.

Attempts have been made to recover the needed fluoride from the gases which are given off in the manufacture of phosphate fertilizer.

These attempts have been frustrated so far by lack of settling space for the dust arising when the ground phosphate is dumped into the bins with the acid. Very little work has been done on this, however.

Segregation and Deoxidation and the Efficiency of Aluminium, Silicon and Titanium as Deoxidizers.

To the Editor of Metallurgical and Chemical Engineering

Sir:—To supplement the notes on the discussion of sound

FIG. 3.—CARBON-DIAGRAM OF INGOT AND BLOOM.

FIG. 7.—SILICON-DIAGRAM OF INGOT AND BLOOM.

FIGS. 3 AND 7 OF DUDLEY PAPER

ingots before the American Institute of Mining Engineers, as reported in your March issue, p. 151, the following remarks which I made in the discussion of Dr. Dudley, seem pertinent.

SULPHUR PRINT STANDARD
OPEN-HEARTH

SULPHUR PRINT TITANIUM
OPEN-HEARTH

In reading the very interesting paper of Dr. P. H. Dudley I noticed on the carbon diagram of an ingot the following carbon determinations:

In Fig. 3, line 9, a normal segregation of from 69 to 73; line 10, a negative segregation of from 69 to 50; line 12, a negative segregation of from 69 to 63; line 13, a negative segregation of from 68 to 65; line 14, a negative segregation of from 68 to 60.

I will endeavor to explain why this negative segregation occurs in the lower half of the ingot and submit as a partial explanation the fact that the segregation is induced by the oxides in solution upon which the carbon of the steel reacts.

In examining the silicon diagram of the same ingot as shown in Fig. 7, it will be found that the silicon is nearly uniform. If we admit for a moment that there are some oxides in solution in the center of the ingot and I will try to show later that it is proper that we should, why were these not reduced by the remaining silicon which is supposed to be such an efficient deoxidizer?

This brings us to a discussion of the comparative efficiency of the three deoxidizers mentioned by Dr. P. H. Dudley and Mr. Talbot, viz.: aluminium, silicon, and titanium.

Aluminium as a Deoxidizer.—Aluminium is the most powerful of all known deoxidizers. It will reduce the oxides of both silicon and titanium, but unfortunately by oxidation it will be converted into alumina, which melts at 2010 deg. C. and consequently is infusible at the temperature of the bath. This fact has received only slight consideration in many quarters.

This infusible alumina will remain in the steel and if some part of it by chance is near the top of the ingot it will cover the surface of the pipe and shrinkage cavity, eliminating any advantage which could be gained from immediate rolling, as suggested by Mr. Talbot. It will be noticed that Mr. Talbot has suggested in "well made steel" an addition of 2 oz. of aluminium per ton, or in the case of a 12,000-lb. ingot an addition of 12 oz., which by oxidation will produce 24 oz. of alumina per ingot; this most infusible material will be disseminated throughout the mass in small shot, which later on will be rolled into streaks.

When such streaks of alumina are present between the metallic crystals of a steel rail they destroy the continuity of the metal, having no strength in themselves they are very readily broken and cracks started from this cause are bound to spread through the adjacent metal when it is subjected to the severe stresses and strains of the heavy wheel loads passing over the rail.

Silicon as a Deoxidizer.—Silicon, as already mentioned, is not a powerful deoxidizer and when added to steel it leaves a remainder in it. Usual determinations of silicon give no clue as to the state in which it is found in the metal, whether as silicides, silicic acids or silicates, but if it exists in either of the two latter forms its presence is exceedingly harmful.

Microscopic examination of rail steel discloses small globules of foreign matter consisting of sulphide of manganese and also of oxides and slags. It has been noticed that very often a steel containing as much as 0.10 per cent of silicon in the form of iron silicide will be wild when poured necessitating an addition of aluminium as a deoxidizer in the molds.

Titanium as a Deoxidizer.—Titanium added to the steel in the ladle, after the silicon, will complete the deoxidation. Heats with an addition of titanium of from 0.05 to 0.10 per cent will not require any additional deoxidizer in the molds.

It is the only deoxidizer known which can be used without danger of leaving any of the products of its oxidation in the bath of steel, as pointed out in Dr. P. H. Dudley's paper.

By oxidation titanium produces titanic acid which will flux the slag in suspension in the steel and if sufficient time be given for the reaction to be completed in the ladle, after its addition, all of the products of its oxidation will rise to the surface leaving a clean steel.

If in the Talbot process such a deoxidizer be used to make pipeless ingots, the pipe being clean will weld more readily when the ingot is compressed.

If a comparison were made between two sulphur prints from the cross section of two rails coming from the same part of two different ingots; the rails being of substantially the same chemical composition but the one having been properly treated with 0.10 per cent of metallic titanium, the other being a plain open-hearth steel, the former would not show any slag inclusion and only a very slight segregation, while the latter would in many instances show a dirty steel "full of slag" and an excessive amount of segregation. This is evident from the adjoining comparative sulphur prints.

It will be noticed that the untreated rail has a silicon content

of 0.15 per cent and it is a fact that a few pieces of aluminium were used in the mold in the production of this steel. If, therefore, silicon is a powerful deoxidizer why should there be such an amount of oxides and slags and consequently so much segregation in this steel? The sulphur print of the rail treated with ferro-carbon-titanium does not show anything of the kind and it is therefore reasonable to assume that the elimination of the oxides will result in diminished segregation.

From the foregoing my conclusion is that for the manufac-

ture of good rail steel silicon, a cheap deoxidizer, ought to be used to a limited extent, but that deoxidation should be completed with titanium, which as mentioned by Dr. Dudley will not only react on the oxides, fluxing the slag, etc., but will also reduce the iron silicates formed in the steel by the previous introduction of ferrosilicon.

As to the impression that rail steel treated with ferro-carbon-titanium pipes, I will say that good steel always pipes and in experimenting along this line I have found, although I cannot as yet give a positive explanation for the fact, that silicon and titanium are antagonistic and that the silicon content in rail steel treated with titanium should be reduced within the limits of from 0.06 to 0.10 per cent, for if the silicon is so reduced it will be found that the shrinkage cavity will be similar to the one shown in Dr. Dudley's paper (see adjoining illustration) and that the cavity will be clean and free from all silicates, slag or alumina so as to increase its welding properties when the ingots are immediately

SPLIT INGOT

bloomed as suggested in Dudley's and Talbot's processes.

The drop and exhausted ductility test, for basic open-hearth steel rails is excellent and we are indebted to Dr. P. H. Dudley for its introduction. Very often, however, a rail rolled from a heat treated with aluminium, in accordance with the ordinary practice or by the Talbot or Hadfield process, might pass the drop test to the entire satisfaction of both the railroad and the mill, but as already explained when I mentioned aluminium as a deoxidizer, such a rail containing streaks of alumina, after a certain length of time in service will develop defects which are very often the real origin of broken rails and consequent wrecks.

I wish to state, however, that I do entirely approve of Dr. P. H. Dudley's specification for the manufacture of basic open-hearth rails but will add, as already explained, that if no aluminium be used (which transformed into alumina will coat both the shrinkage cavity and the pipe) the steel bloomed under its equalized initial heat will be rendered pipeless by the usual discard of from 8 to 10 per cent.

Niagara Falls, N. Y.

N. PETINOT.

Nichols-Hesse Dinner

On the evening of Saturday, April 19, a complimentary dinner was given by the chemists of the United States to Dr. William H. Nichols, the president of last year's International Congress of Applied Chemistry, and to Dr. Bernhard C. Hesse, the Secretary of the Congress, as a mark of their appreciation and affection. The dinner was held at the Chemists' Club in New York City, and as some 225 men had come to do honor to the two men who more than any one else bore the brunt of the battle and made the Congress a success, the large lecture room (Rumford Hall) had been chosen for the occasion. It was not by any means merely a New York City affair. The names of the diners as well as of the speakers showed that American chemistry was broadly represented.

That the Chemists' Club as a social institution is fully up to date in every respect, was evidenced by the fact that just before the beginning of the dinner the extra waiters which had been engaged for the evening went on a strike. But it is also a fact that the House Committee settled the strike quickly and that very few of those who sat down to dinner in the prettily decorated hall realized what a narrow escape there had been

on his success. As Mr. Little explained this was one of the rare occasions of this kind which ended with a surplus instead of a deficit. This result was mainly due to Mr. Matheson's highly effective work as treasurer. At the concluding meeting of the organization of the Congress, held just the night before, \$2,000 out of the surplus had been granted to the Chemists' Club.

Mr. C. O. Mailloux read some twelve official letters of congratulations to Drs. Nichols and Hesse from French and Italian societies.

Then the speech making proper began. Dr. Wilder D. Bancroft, of Cornell University, spoke as Past President of the American Chemical Society and of the American Electrochemical Society. He spoke exceedingly well, both concisely and to the point. Starting with a funny church collection story, he passed to a review of the success of the Congress—for it was a great success—and of the men who made it such. Morris Loeb lost his life at it. Dr. Rosengarten nearly did. Mr. Matheson produced a surplus and Dr. Hesse gave up a year and a half of his life to produce thirty volumes of Transactions and a great many tons of literature. And as to Dr. Nichols'

WILLIAM H. NICHOLS

BERNHARD C. HESSE

from a somewhat awkward situation. Well, everything went along lovely. The dinner was excellent and greatly enjoyed. It was simply representative of the potentialities of the cuisine and the wine cellars of the Chemists' Club on one side and of the congeniality of American chemists on the other.

After the dinner was over, the assemblage was graced by the presence of a number of ladies gathering on the balcony of the banquet hall. The speechmaking began and lasted till after midnight.

Dr. Chas. Baskerville, of the College of the City of New York, for the Committee of Arrangements, introduced Dr. Edward W. Morley, of West Hartford, Conn., as the presiding officer of the evening. Dr. Morley who had been the Honorary President of the Eighth International Congress, made a felicitous little speech and concluded by introducing in turn Mr. Arthur D. Little, of Boston, Mass., as the toastmaster of the evening.

Mr. Little spoke humorously and feelingly of the achievements of the Congress and of the rôle which the personal element had played in it, of the work of Nichols and Hesse, and of the tragic death of Morris Loeb.

At the conclusion of his introductory speech Mr. Little read a long series of messages, including letters from Dr. Chandler, Dr. Remington, Mr. Kuttroff, Mr. Adamson, Dr. Bogert, Dr. Cameron, and Mr. Wm. J. Matheson. Mr. Matheson had been the treasurer of the Congress and a toast was drunk to him

work as president, if we should ever go again through such a Congress in our life-time (which Heaven forbid) and if we should be forced to get along without Dr. Nichols as president (which Heaven forbid)—we might think in poetry:

Twinkle, twinkle little star—
Riding on a trolley car—
Trolley car went off the track—
Gee, I wish we had our Nickels back.

The next speaker was Dr. William Brady, of the Illinois Steel Company, of South Chicago, Ill., who represented the American manufacturers. He spoke of the American manufacturer as a business man. His first concern is the quality of his product and he educates the American public in quality. Then he looks for quantity and systematizes and organizes. Now he is very much interested in his men and their safety. If it is possible to go to extremes, the American manufacturer is willing to go to extremes in the matter of safety of his employees. Dr. Brady concluded with a happy reminiscence from early life in a country school.

Mr. Little then introduced Dr. Leo. H. Baekeland, of Yonkers, N. Y., as Past President of the American Electrochemical Society and of the American Institute of Chemical Engineers ("the only aristocracy among American chemical bodies"), as the discoverer of velox paper and the "anonymous discoverer of bakelite," "but the discovery which has most endeared him to his friends was his discovery of Mrs. Baekeland."

Dr. Baekeland in his happy speech asked: "Was it worth while?" Answers to questions as to worthwhileness depend on the point of view. If different viewpoints were not possible, if viewpoints could not be exaggerated, honest men could not differ in discussions at all. But as applied to the past Congress, different viewpoints were hardly possible. He pitied anybody for whom the Congress had not been very much worth while. Of course, those will be disappointed who want to get more out of the world than they put into it. The man behind the machinery and organization was Dr. Nichols. Dr. Nichols' work at the Congress has been a school for every one of us. "I had a bully good time."

Dr. David T. Day, of Washington, D. C., spoke of the Congress as a lightning express on its way to Russia. Hesse was at the switch and got the proceedings of the Congress out before the Congress began to proceed. It was a wonder what it is possible to get out of a Hessian crucible. The calm spot in the center of the cyclone was Dr. Nichols. The inspiration came from him. He put the different men together and made

Dr. B. C. Hesse had before him a complete bound set of the *Transactions* and told something of the troubles which he had to meet as the secretary of the Congress. But from his statistical figures it seemed that out of eight there were seven men satisfied and only the eighth one was disappointed. The documentary evidence produced by Dr. Hesse as to the reasons why some were disappointed was truly amusing. "Get the eighth fellow to do as the rest of us do." Dr. Hesse concluded with hearty words of thanks to Dr. Nichols and to the chemists of the United States.

A toast drunk to the president of the Ninth International Congress of Applied Chemistry, Dr. Walden, in St. Petersburg, concluded the evening, which will long be remembered.

In the following we give the alphabetical list of those who participated in the celebration in honor of Dr. Nichols and Dr. Hesse:

L. Albrecht, C. Amend, O. P. Amend, T. Armstrong, F. W. Atkinson, W. S. Ayres, L. H. Baekeland, F. H. Baldwin, W. D. Bancroft, C.

PHOTOGRAPH TAKEN AT NICHOLS-HESSE DINNER

them work, and while he worked very hard in doing so, he was not used up himself. That is, he was the catalytic agent. Nickel as a catalytic agent may tire at times. Nichols does not, being a plural and representing a polymerization product, Dr. and Mrs. Nichols. In order that Dr. Nichols and Dr. Hesse should take with them into later life the memory of the appreciation and affection of their American fellow chemists Dr. Day presented, in the names of the American chemists, to Dr. Nichols a counterpart in silver of the desk set in the Royal Treasury in London and to Dr. Hesse a silver loving cup.

Dr. William H. Nichols, in his gracious words of appreciation, pointed out as one great lesson of the Congress the enormous amount of ability and chemical knowledge stored up in our universities, colleges, laboratories all over the country, and the enormous amount of hard and untiring work done there in a quiet and unostentatious way. He pointed out that this work needs more encouragement. He pledged his aid to render it possible in future to make the most of this work of college professors for the good of their students and the good of the world. This being a true problem of "conservation," nothing of these vast intellectual resources of the country should go to waste.

International Geological Congress

The Twelfth International Geological Congress will meet in Toronto, Canada, from August 7 to 14, 1913. The headquarters will be at the University of Toronto.

The membership fee is \$5.00.

Titles of papers and proposals to be presented should be submitted to the General Secretary, R. W. Brock, director of the Geological Survey of Canada, Ottawa, Ont., Can., as early as possible. Contributions must be received by May 1st if they are to be printed in time for distribution before the meeting.

The official language of the Congress is French, but contributions may be submitted in French, English or German.

The following topics have been selected by the executive committee as the principal subjects for discussion: Coal resources of the world; differentiation in igneous magmas; the influence of the depth of the character of metalliferous deposits; the origin and extent of the pre-Cambrian sedimentaries; the sub-divisions, correlation, and terminology of the pre-Cambrian; the extent of which the ice age was broken by inter-glacial periods; the physical and faunal characteristics of the palaeozoic seas, with reference to the value of the recurrence of seas in establishing geological systems.

A great many different excursions have been arranged, preceding the sessions of the Congress, during the sessions, and after the sessions. Details concerning the same may be found in the second circular issued by the Congress. This circular as well as all other information may be obtained from the Secretary of the Twelfth International Geological Congress, at the Victoria Memorial Museum, Ottawa, Ontario, Canada.

Electrochemical Spies in Niagara Falls

A mild sensation has been recently caused in Niagara Falls electrochemical circles by the capture of a Norwegian engineer in the act of making drawings and notes in one of the larger plants. An examination of the man's effects brought to light data from a number of plants in Niagara Falls and elsewhere.

His mode of procedure was to get a job in a repair gang thus securing access to more departments than would be possible in special work. Two accomplices went about the country with this chief, following the same lines.

A confession by a compatriot in one of the plants brought out the fact that money was plentiful and was freely used where necessary. From the same source it was hinted that large foreign interests were responsible for the presence of these spies and financed the operations liberally. One of the names used at Niagara Falls by this man was Kverne, those of the assistants, a Swede and a German, not yet having been obtained.

Publicity is given these facts as a warning to manufacturers, as the considerable ability of this engineer, evidenced in his notes, makes his presence dangerous in plants where secrecy is considered essential.

Closing of Norwegian Electric Iron Ore Reduction Plant

The Electric Iron Smelting Company Hardanger, of Norway, has been forced, after three-quarters of a year's operation, to close down its factory, according to information published in Scandinavian newspapers. The iron smelting process used by the Hardanger company was the well-known electric shaft furnace process developed by the Swedish engineers, Grönvall, Lindblad and Stalhane, and which is in successful operation at different steel plants in Sweden.

The news that the Hardanger plant has been closed may appear startling, contrasted with the successful operation of furnaces of the same type in Sweden. The reason is due to inavailability of suitable raw materials in Norway. The

Swedish electric-blast furnace has to be charged with charcoal, which is readily available in Sweden, while the Norwegian plant was using coke, since charcoal was not obtainable at the plant at a reasonable price.

During the experimental work of developing the electric-shaft furnace at Trollhattan coke was found unsatisfactory in the operation of the furnace, so the closing of the Hardanger plant only confirms earlier results.

The Hardanger company owns the water-power which was used for the electric smelter, amounting to 14,000 hp, and have leased it to a French company, which will utilize it for electrochemical industries.

The Non-Ferrous Metal Market

Since our last report the non-ferrous metal market has been affected by industrial and political conditions both in this country and abroad. Floods and the prospect of tariff changes have combined to affect the domestic spelter market; Mexican revolution has resulted in reduced exports of lead from that country to Europe, with a consequent advance in the foreign market, which was later accentuated by labor strikes in Australia; the tin market has been subject to wide fluctuations, but the copper market has become steadier.

Copper.—The depression which was manifest in March was removed in April. The influence of heavy buying in Europe was felt in the domestic market, where most of the business was for foreign trade. The statistics for March, which were published early in April, were rather favorable, and the situation is considered much improved. The last quotations are 15.35@15.55 cents for Lake, and 15.20@15.30 for electrolytic.

Tin.—Although the foreign market was subject to wide fluctuations in the latter part of March and the first part of April, the publication of the March statistics produced an optimistic tone in the market, and prices have become firm at about 48½ cents, New York.

Lead.—The foreign market has been very firm on account of conditions reported from Mexico and Australia, but the domestic market is quiet and unchanged at 4.30@4.35 cents, New York, and 4.15@4.20 cents, St. Louis.

Spelter.—Sales have been effected only at concessions, and the market has declined. Production has been heavy, and plenty of metal is available for sale. A large tonnage has been sold. The last quotations are 5.70@5.80 cents, New York, and 5.55@5.65 cents, St. Louis.

Iron and Steel Market.

The iron and steel market lost tone quite decidedly in April. Conditions had been practically stationary for an unusually long time. Prices of finished steel products had ceased to advance early in October and after a gradual speeding up the mills reached a state of operating at full capacity at about the same time. The placing of contracts for forward delivery reached a high point in October, dwindling thereafter, while during the first three months of this year contracting was uniformly light. In the late months of last year specifications against contracts were extremely heavy, greatly exceeding the shipments, while during the first three months of this year they ran quite uniformly at a rate approximately equalling the shipments.

Thus since October as to prices and the productive rate, and since the beginning of the year as to contracting and specifying, the steel situation had shown no change. In April a definite departure occurred, but the departure was of such a nature that we describe it as merely a loss in ton. Production continued at the full rate. Prices did not recede. Specifications decreased, falling definitely, though but slightly, below the current shipments. Contracting for forward delivery ceased almost entirely.

The mills had a very large amount of business on books in the form of actual specifications, and the decreased market activity of April did not impair their position, as to the rate of production or as to prices. Continued for two months longer.

the condition probably would do so. In some finished products the mills are booked far beyond midsummer, but without an improvement over April conditions the situation would be impaired by July 1 in some directions.

Whether this relative dullness will continue for a considerable time is naturally dependent upon the causes which produced the condition. In the trade, the common theory is that the tariff discussion is responsible, and if so a definite improvement could hardly be expected for several months. A closer analysis would suggest that there is at least one other cause, that being a psychological one, but one nevertheless susceptible of analysis. In the long run materials make the market, but the market as one finds it from week to week is made by men, not by materials. It proceeds by great movements, for a period upward and for a period downward. The upward movement occurred last year. Then came an anomaly: for six months there was substantially no change in prices, and very little change in general conditions. So long a period of unchanged prices was abnormal, a definite change being overdue. There was not enough latent strength in the situation to produce a fresh upward movement, hence it was natural that the market should lose tone instead. The upward movements are assisted by the price advances, which encourage buyers to contract ahead; with unchanged prices they are not so moved.

While the market has lost ground, it stands in no great danger. The mills are well booked ahead, as to the total tonnage, though here and there are mills with only a little tonnage. There is no danger of cancellations, for nothing new has occurred. A year ago well posted men were convinced that the Democratic party would be successful, and that it would revise the tariff this year, substantially along the lines now proposed. If there is no material improvement from the market condition of April, a slight decrease in production will occur during the midsummer months, but a relatively high rate of activity is assured until almost the close of the year. The serious doubt is as to next year, rather than as to the next six or eight months.

Pig Iron.

The dullness in the pig-iron market continued through April, and was accompanied by somewhat more rapid declines in prices. These declines began late in December, activity having decreased in October and November, but in the first three months of the year the pig-iron market as a whole, averaging all grades and all districts, lost in prices by only about 25 cents per ton per month. In April the losses were at double or triple this rate. The pig-iron decline has been due to psychological rather than material causes. In the first place, producers marked prices up too rapidly, in the late months of last year, having regard to the rate of demand and the large amount of idle capacity. Production by the merchant furnaces increased rather rapidly from October to February inclusive. Once it became established that prices were not to advance further, buyers adopted their usual waiting attitude, and a period in which buyers bought more than their current consumption required, making purchases for further forward delivery, was succeeded by a period in which they bought practically nothing. The declining prices have confirmed them in their attitude. No new thing occurred in April, for as early as February it became certain that a fresh buying movement would not occur until there had been the usual test of strength, by prices declining to a point which would find some furnaces going out of blast or would find some buyers forced to purchase. That test has not yet occurred, but it will probably occur soon. Production is stationary, consumption is undiminished and if stocks as a whole are increasing they are increasing very slowly, for in some districts, notably the Pittsburgh-valley district they are lower than for a long time. Prices are down nearly to the cost of production at many furnaces now operating. We quote: Bessemer, \$17; basic, \$15.75; malleable, \$15.50; No. 2 Foundry \$15.25; forge, \$14.75. f.o.b. valley furnaces, 90 cents higher delivered Pittsburgh; foundry iron at Philadelphia, \$17.25; Buffalo, \$15.50. Cleveland, \$16.25; Chicago, \$17; Birmingham, \$12.50.

Steel.

The floods of late March in the Central West caused a total loss in steel output of more than 250,000 tons, which fell largely in mills producing billets and sheet bars, as a result of which the supply in April was poorer than ever. Prices are nominally unchanged at \$29 for billets and \$30 for sheet bars and rods, at maker's mill, Pittsburgh or Youngstown. In resuming after the floods the blast furnaces led the steel works, so that the steel works are in comfortable position as to pig iron. About one-half of all the sheet and tin mills were closed on account of flood, and their resumption was retarded by poor deliveries of steel. A Youngstown interest has sold several lots of sheet bars, aggregating 25,000 tons or more, for second half delivery at \$27.50, maker's mill, but this seems to exhaust its offerings, and the only market quotable is that for relatively early delivery, given above.

Finished Steel.

Premiums for finished steel products for early delivery are quite unusual, except that plates usually command a premium of \$1 to \$2 a ton and merchant steel bars bring prices up to 1.75 to 2 cents, depending on quantity. Regular mill prices are given below. Under date of April 12 the National Tube Company issued a new list, advancing steel pipe by about \$1 a ton, and the new list was adopted by independents, eliminating the slight concessions which had been given from the old list by several mills. Slight shading in sheets and tin plates disappeared in April, on account of the flood decreasing production, but on galvanized sheets the shading reappeared, to the extent of \$2 a ton.

Regular prices at Pittsburgh, unless otherwise stated, are as follows:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f.o.b. mill, except Colorado.
Plates, tank quality, 1.45 cents.
Shapes, 1.45 cents.
Steel bars, 1.40 cents, base.
Steel hoops, 1.60 cents, base.
Common iron bars, 1.65 cents, Pittsburgh; 1.67½ cents, Philadelphia; 1.57½ cents, Chicago.
Wire nails, \$1.80 per keg, base; plain wire, 1.60 cents.
Sheets, blue annealed, 10-gage, 1.75 cents; black, 28-gage, 2.35 cents; galvanized, 28-gage, 2.40 to 2.50 cents; painted corrugated, 2.55 cents; galvanized corrugated, 3.55 cents.
Tin plates, \$3.60 for 100-lb. cokes.
Merchant steel pipe, ¾-in. to 3-in., 70½ per cent off list.
Steel boiler tubes, 3½-in. to 4½-in., 70 per cent off list.
Standard railroad spikes, 1.80 to 1.85 cents.
Button-head structural rivets, 2.10 to 2.20 cents; cone-head boiler rivets, 2.20 to 2.30 cents.

The Western Metallurgical Field

Labor Strike at Globe Smelter

The beginning of April witnessed a labor strike at the Globe plant of the American Smelting & Refining Company, Denver. The Western Federation of Miners induced the men to walk out and demand more pay and better working conditions. The strike continued for a week or ten days, during which time the smelting furnaces were banked or run at such capacity as could be maintained by the technical staff of the plant. The smelting company refused to treat with the Western Federation, but offered to listen to a delegation of the strikers. After being out about ten days, the strikers returned to work, and the plant is again running at usual capacity.

An investigation of the conditions at the smelter indicated that they were not as bad as claimed by the Federation, neither were wages as low as stated. Another rumor and press report, which proved to be untrue, was to the effect that the strikers who returned to work did so at reduced wages.

Prospecting for Potash in Death Valley, Cal.

Preliminary results of the Geological Survey's drilling in Death Valley, California, have now been reported, and the following brief summary is issued:

Reports state that practically the entire area in Death Valley has lately been located as "potash" claims, presumably as association placers, but in blocks of very large area. It is said that a single tract of 17,120 acres, known as the Kali property, was located in May to July, 1912, on the lowest part of the valley. Other groups both north and south of this tract have subsequently been taken up. A vast amount of saline matter is accumulated on and beneath the floor of Death Valley, and it is logical that this area should have been one of the first to attract attention in the search for soluble potash salts.

Four wells have recently been drilled by the Geological Survey to test the general character of the deposits that lie beneath the floor of this valley. Three of these wells were placed in the area of smooth salt in the lowest depression of the valley. The fourth was located in the area of rough salts about 20 miles north of the others. The records of all of these holes are very much alike. These borings are believed to be the first information that has been obtained concerning the character of the deposits underlying the floor of this valley.

Eighty-three samples of muds, salt crystals, and waters or brines have been preserved from these borings for further chemical examination. The preliminary results, given in the accompanying table, include only potash determinations made on natural brines collected from the beds that yielded the principal flows. The analyses are by W. B. Hicks and R. K. Bailey.

Description of Sample	Depth in Feet at Which Sample Was Taken	Total Salts in (Ignited Residue) Percent- age of Original Sample	Potash (K ₂ O) in Total Salts Expressed as Percent- age of Ignited Residue	Potassium Expressed as Percent- age of KCl in Original Solution

A vast amount of saline material is accumulated in the bottom of this valley, but the mode of its deposition probably is not favorable to selective crystallization on a large scale. Segregation of potash or any other portion of the soluble constituents of the waters may have taken place to a slight extent in the individual salt crust layers, but under the conditions described any such differentiation is likely to have been restricted to the individual layers as units, and therefore has occurred on a scale so small as to be of doubtful practical importance. It seems evident that unless a vast body of saline material has been deposited at one time during a single period of desiccation that there would be little chance for the various dissolved constituents to become segregated one from another on a large scale. There is no record of the drying up of a single large lake of saline waters in Death Valley. Although it is possible that the shores of such a lake might have been completely buried, the assumption that this may have happened must be purely a matter of speculation. Similar reasoning may apply to many other areas in the desert basin region. Great interior lakes have existed in certain areas and may have dried up under such conditions that the salts they contained were deposited in a great body and that the potash and other minerals in the waters were to a certain extent segregated in some portion of the deposits by crystallization. Searles Lake contains a deposit of salt evidently produced in this way, and others may be found, although they are not now exposed at

the surface. It does not appear that there is much theoretical justification for the belief that such deposits must be present in Death Valley. It is, of course, possible that the present conclusions are based on insufficient negative evidence, and for this reason any further drilling that may be carried on by private claimants in the Death Valley region should afford a record of much importance and interest in this connection.

Tendencies in Concentration

In a paper recently read before the Colorado Scientific Society, Mr. Edward S. Wiard, of Denver, gave the following classification of concentrating ores, based on the degree of crushing required to unlock their constituent minerals:

Class A. Ores yielding on a coarse initial break, clean concentrate and clean tailing for the large size (between 1¼ in. and 10-mesh), and similar products in the sand and slime sizes.

Class B. Ores yielding on a coarse initial break, large size clean concentrate, large size clean tailing and large size middling.

Class C. Ores yielding on a coarse initial break, large size clean concentrate and a corresponding middling.

Class D. Ores yielding on a coarse initial break, large size clean tailing and a corresponding middling.

Class E. Ores yielding on a coarse initial break, nothing but large size middling; and as a sub-class, ore yielding two or more grades of large size middlings.

The definition of the first three classes indicates a brief outline or flow-sheet for the treatment of a majority of ores. Examples of Class A ores are very rare; but recently a good example has come to light in an ore containing 13 oz. zinc per ton, 12 per cent lead and 32 per cent zinc. On crushing coarsely to a limiting size of about 10 mm., screening and classifying, the screen sizes were jigged and the classified products treated on tables. The jigs yielded clean lead concentrate of 63 per cent lead and zinc concentrate of 48 per cent zinc. The jig tailing contained only 1 per cent lead and 6 per cent zinc. Similar products were obtained from the tables, the slimy discharge from which contained only 1.2 per cent lead and 13 per cent zinc, amounting to only 3 per cent of the total mill feed. The approximate percentage saving for the whole operation was 88 per cent of the lead, 90 per cent of the zinc and 85 per cent of the silver.

In large size mills, say above 100 tons capacity, there is a tendency to abandon the familiar trommel line in favor of one or more sets of splitting screens which divide the feed into oversize and undersize for direct feed to jigs. The reason for this trend is found in the excessive cost of maintenance of trommel lines, the time lost in repairs, and the inefficiency of the device under large loads, with the accompanying tendency for the feed to build up at certain points in the system.

In jigging practice the criterion has been the production of concentrate, and it has been commonly believed that unless a shipping product could be made, jigging was not profitable. It is possible, however, by jigging, to produce an enriched portion for subsequent fine regrading without very much loss, and the enriched portion could be concentrated to the same tailing that would obtain if all the ore had been ground fine before separation. Jigging in such a case would give a greater total saving, and the required equipment would be less.

Company Reports

The American Smelting & Refining Company's fourteenth annual report, for the calendar year 1912, contains little or no matter of general interest. From the financial figures submitted it appears that the company had a profitable year, but the balance of the report lacks detail and definiteness. As an incentive to good service on the part of employees, the company appropriated the sum of \$307,822 for distribution as a cash bonus. A new pension system has been adopted whereby male employees who have reached the age of sixty-five years and female employees who have reached the age of sixty years, and who have been continuously in the employ of the company, or of acquired companies, for twenty years, may be retired. The

amount paid to pensioners will be based on an allowance of 1 per cent for each year of service of the average annual pay during the ten years next preceding retirement, but no pension will exceed \$200 per month or be less than \$20 per month. A sum of \$500,000 will be invested to meet the requirements of this system.

The Mount Morgan Gold Mining Company, Ltd., Queensland, Australia, has made public the report of the general manager, Mr. Benjamin Magnus, for the half year ended Nov. 30, 1912. The operations in the mine were very satisfactory and were attended by a gradual reduction in cost. The copper smelter treated the following tonnage of ore:

	Tons treated	Copper produced tons	Gold produced oz.
Copper ore	93,783	3,276	42,744
Gold ore	19,895	530	18,831
Many Peaks ore.....	54,394	894	413
Purchased ore	178	23	9
Miscellaneous	4,173	282	555
Total.....	172,433	5,005	62,552

The permanent closing of the Mundic works has caused the smelter to handle the silicious ore formerly treated there. This has increased the cost of producing copper, but the increased gold value of the blister copper gives greater net returns on the operation. A new smelting plant has been started, entirely independent of the old plant, and will embody the latest ideas in modern copper smelting. This new plant is warranted not only on account of the increased net return which will result, but also by the life of the mine. In the meantime improvements are being made at the old plant so that costs there will be cut down as far as possible. Mr. Robert Sticht is assisting Mr. Magnus in the design of the new plant.

The Goldfield Consolidated Mines Company, Goldfield, Nev., effected material reduction in costs during the year 1912, according to the sixth annual report of that company. The ore produced from the mine had an average value of \$19.77 per ton, while the average gross realization from ore treatment was \$18.40 per ton. Costs were reduced by \$1.36 per ton; the noteworthy items of reduction being, milling, 28 cents per ton; marketing concentrates, 61 cents; marketing bullion, 8 cents; general expense, 10 cents. The total expense of milling was \$1.61 per ton; concentrate treatment, \$0.38; marketing bullion, \$0.07. The net realization from operations was \$11.75 per ton. This amounted to 59.44 per cent of total production. The operation of the concentrate treatment plant increased net profit from milling operations approximately 50 cents per ton of ore milled.

The Miami Copper Company's annual report for 1912 states that the sixth and last section of the mill was started about the last of February and that the average tonnage treated per section per day was 489 tons of ore. The ore has proved hard to crush, and rigid rolls have been replaced by heavy spring rolls, and the Chilean mills by Hardinge pebble mills. Two important experiments were conducted during the year. The first showed that no greater extraction or reduced cost could be obtained by using the so-called "roughing" process. The second, which is still in operation, indicates that a re-treatment process, consisting in regrinding the coarsest sands from the sand-floor reject and middling, followed by classification and table treatment, will give an increased saving of about 1½ lb. copper per ton of ore. The net smelter returns of refined copper amounted to 32,832,609 lb. Based on this return, the cost of refined copper in concentrate on board cars at Miami, was \$0.06477 per lb.

The Old Dominion Copper Mining & Smelting Company has issued its annual report for 1912. The following items relate to metallurgical operations. Concentrating ore treated in 1912, was 166,870 tons containing an average of 3.37 per cent copper, as compared with 130,230 tons of 3.99 per cent grade in 1911. The costs for 1912 were, nevertheless, lower than for 1911, being \$0.753 and \$1.012 per ton, respectively. Smelting costs for 1912 were \$2.304 per ton of new charge smelted, as

compared with a similar cost of \$2.568 in 1911. The cost of converting per ton of fine copper was \$9.45 in 1912, and \$8.26 in 1911. Included in the 1912 cost is an item of \$13,500 for improvements. The old practice of carrying converter fumes directly into the furnace flue-dust chamber was abandoned, and a new flue-dust chamber was erected for converter gases. In six months the recovery of dust has amounted to 34,000 lb., averaging 45 per cent copper. Over 87 per cent of this was finer than 200-mesh, and would have been lost under the old system. The first unit of a basic converting plant has been installed, being of the Great Falls type, and it is expected that converting costs for 1913 will be materially reduced.

The fifth quarterly report of the Chino Copper Company, covering the fourth quarter of 1912, shows a total production of copper for the year of 29,237,966 pounds. Each succeeding quarter of the year showed an increase in tonnage treated and copper produced. During the fourth quarter the quantity milled was 452,650 tons of ore, averaging 1.841 per cent copper, yielding 10,781,621 lb. copper. The grade of ore was lower than for the preceding quarter when it averaged 2.33 per cent copper. The total net profits from all sources for the year was \$2,352,822. The earnings for the fourth quarter were calculated on an average price of 14.532 cents per pound of copper. The cost per pound of net copper produced, after making smelting deductions, was 8.49 cents per pound, as compared with 6.57 cents for the preceding quarter. This increased cost is due partly to the ore treated, which contains a large percentage of iron, thus giving a lower ratio of concentration and lower grade of concentrate. The ratio of concentration was 15.14:1, the concentrate averaging 18.03 per cent copper as compared with an average of 25.02 per cent for the preceding quarter. The average extraction for the quarter was 64.58 per cent, compared with 65.15 per cent in the preceding quarter. The fifth section of the mill was put in operation November 28, 1912, but practically only four sections have been in operation during the fourth quarter on account of making improvements.

The Ray Consolidated Copper Company's report for the fourth quarter of 1912 shows that the gross production for the year was 35,861,496 lb. copper. The average grade of ore treated during the fourth quarter was 1.6737 per cent copper, which is about the average for the year. The extraction was 68.102 per cent, compared with an extraction of 68.2783 per cent for the whole year. The average cost per pound of net copper produced during the quarter was 9.828 cents, as against a cost of 10.047 cents for the first three quarters. During the quarter six sections of the mill at Hayden were in operation. The seventh section is now available, and the eighth is nearing completion.

In the annual report of the Arizona Copper Company for the year ended September 30, 1912, the general manager gives the following data regarding the operation of mill and smelter. During the year 782,100 tons of ore were concentrated, the ratio being 6.74 tons into 1. Improvements in the concentrating plant raised the daily tonnage from 907 tons per running day in the previous year to 1573 tons last year. Concentrate re-dressing plants were installed at both mills last year, for the purpose of making a higher grade, cleaner product. At the oxide ore concentrator and leaching plant 108,230 tons of ore were treated, yielding 89,800 tons of tailings which were treated in the leaching plant. This treatment yielded 0.71 per cent of the total copper production.

In the smelting department the average yield from ores and concentrates was 12.03 per cent copper. The elimination of silicious matter in the re-dressing plant at the concentrator reduced the amount of flux required, increased the capacity of the furnaces and effected an economy in smelting. In the converter department one converter was run with basic lining, the operation being so successful that the remaining converters have been changed to conform to that practice.

The erection of the new smelting works is progressing rapidly, and it is expected that operation will commence in late summer or early autumn. The prospective date of completion and operation is considerably earlier than expected.

Evolution in Methods of Handling Slime—II

By H. N. Spicer

New Zealand is an interesting country from a metallurgical point of view, particularly on account of its contribution of the tall, pneumatic-slime-agitation tank to the cyanide industry. This device is the invention of F. C. Brown and S. D. McMiken, of the Komata Reefs mill, where the first of these tanks was built and used for the agitation of ore slime. Owing to the fact that this tank was first adopted in North America at Pachuca, Mexico, it has come to be more commonly known as the Pachuca agitator, thus in a way detracting from the credit due to its inventors and the country of its origin.

It will be apparent from the following notes that the methods of handling slime in New Zealand are much more advanced than those described in the preceding paper on India, in which country the crudest methods have prevailed up to the present time. As in other countries, certain typical features have been

ders which carry off the clear water. In the center of each tank is a vertical shaft with a heavy wooden arm attached at the bottom, the whole being slowly revolved by an overhead gear. Near the periphery of the bottom of the tank is a 4-in.

FIG. 2.—REINFORCED CONCRETE PACHUCA TANKS, WAIHI MILL

valve which is opened at intervals of half an hour for the discharge of accumulated thick slime. This product contains about $1\frac{1}{2}$ parts of water to 1 of solids. It is then mixed with cyanide solution and pumped to Pachuca agitators.

These agitators are worth more than passing mention, as they are built of reinforced concrete, 55 ft. high and 13 ft. diameter, inside measurements. The walls are 5 in. thick; but similar tanks at another mill have been built with only 4-in. walls, and have proved satisfactory. The reinforcement is old rails and wire rope, the latter being woven horizontally through the former which stand vertical. The cost of these tanks was appreciably lower than the bids for similar steel tanks, indicating that under certain conditions where cement and labor are comparatively cheap, it may prove profitable to build concrete agitators. A closer view of the agitators is given in Fig. 2.

A different procedure obtains at the Waihino mill of the same company, shown in Fig. 3. Sand and slime are separated in spitzkasten, the former being shovelled into filter-bottom concrete tanks and leached with cyanide solution. The slime from the dewatering cones, containing about $1\frac{1}{2}$ parts water to 1 of solids, is further dewatered by vacuum filters which reduce the moisture to about 30 per cent. These filters are of the stationary Moore type. After a cake has been formed, the vacuum is cut off and the slime allowed to fall back into the tank. If necessary, compressed air is blown into the leaves to aid in dislodging the cake. The tank has a V bottom, terminating in a goose-neck through which the sludge is periodically withdrawn into a mixer where cyanide solution is added.

The slime is then elevated to steel Pachuca tanks by means of two-stage tailing wheels. The agitators are without the

FIG. 1.—WAIHI MILL, WAIHI GOLD MINING COMPANY

developed in New Zealand cyanide practice, which are common to all the mills and distinguish them from others.

The Waihi Mills

The Waihi mine is the largest in New Zealand, and the ore is treated in two large mills. The Waihi, of 90 stamps, and the Waihino, of 200 stamps. At both mills the ore is crushed in water, thus introducing the necessity of dewatering before cyaniding.

At the Waihi mill, shown in Fig. 1, the stamp pulp, containing from 7 to 9 tons of water per ton of ore, is elevated by wheels to spitzkasten, 4 ft. square and 4 ft. deep, two of these being arranged in series for each twenty stamps. The separated sand is reground in tube mills, and after amalgamation and concentration, is classified in other spitzkasten. The sand pulp is run to circular collecting vats previously filled with water. Any slime accompanying the sand flows out of the vats and is returned to the main separating cone. When the sand vats are full they are allowed to drain, after which the sand is leached with cyanide solution.

The slime, 90 per cent to 95 per cent of which will pass a 200-mesh screen, flows to a set of dewatering cones, 5 ft. square and 5 ft. deep, in which the pulp is thickened to a consistency of three or four parts of water to one of solids. This thickened slime is further dewatered in a device peculiar to this plant. It consists of three flat-bottom settling tanks, 32 ft. diameter and 18 ft. deep, provided with annular overflow laun-

FIG. 3.—WAIHINO MILL, WAIHI GOLD MINING COMPANY

customary central lift-pipe, but are found to give good results. The pulp is agitated for about 7 days, with air at 40 lb. pressure. The great length of time required for agitation is mainly to effect solution of the silver.

Moore type vacuum filters are used at both these mills. Their construction suggests an interesting departure from the usual custom, corrugated steel sheets being substituted for the ordinary cocoa-matting center.

Concentrates from these mills are treated by cyanidation after being reground impalpably fine. The pulp is agitated for fourteen days in high, narrow tanks, and then filtered in plate and frame presses. The extraction is about 94 per cent.

Waihi Grand Junction Mill

The present practice at this mill represents an interesting development from the separate treatment of concentrate, sand

FIG. 4.—WAIHI GRAND JUNCTION MILL

and slime, to a system in which all the ore is treated as slime. With this development came the adoption of crushing in cyanide solution, this being one of the few mills in New Zealand to adopt this practice. Preliminary dewatering of the slime is thereby avoided, and the time of treatment is shortened by the more rapid solution of the precious metals during the crushing and grinding process. The mill is shown in Fig. 4, at the extreme right of which can be seen the tall agitators.

The ore treated here is practically the same as at the Waihi mill, and the process consists in crushing by stamps, separating sand from slime in cones, regrounding the sand in tube mills which work in a closed circuit with cones, settling and agitating the slime, and filtering by vacuum. The underflow of the cones is run over the Willey tables formerly used as concen-

FIG. 5.—TALISMAN MILL, KANGAHAKE, NEW ZEALAND

trators when concentrate was treated separately, but now used merely as classifiers to separate some fine sand for return to the tube mills.

The slime separated by the cones contains about 10 parts cyanide solution to one of solids, about 95 per cent of the latter being finer than 200-mesh. It is settled in cone-bottom tanks, 22 ft. diameter, the clear overflow from which is returned into the mill system. The thickened pulp is drawn continuously from the bottom of these settlers, having a consistency of about $1\frac{1}{2}$ parts solution to 1 of solids, and is

pumped to a series of flat-bottomed storage agitators fitted with stirring arms revolving at 4 r.p.m. From these the pulp is pumped to the high agitators, which are without the usual central lift-pipe. Air is used at 38 lb. pressure, and the time of agitation is 18 hours, the latter having been reduced from a period of several days. This is an improvement which may be ascribed, in part, to the practice of crushing in solution. Vacuum filtration in a Moore filter completes the slime treatment.

The Talisman Mill

The principal features in handling slime at this mill are the use of diaphragm cones for classification, and huge spitzkasten for dewatering. The latter may be seen in Fig. 5, at the top of the lower building. The ore is stamped in water, and classified into sand and slime in diaphragm cones, the diaphragm being near the bottom, with a $\frac{1}{2}$ -in. space all around. These discharge a thick pulp, about one to one, which is ground in tube mills, combined with the overflow of the cones, and again classified in a second set of diaphragm cones, the underflow of which is returned to the tubes. The overflow from the second set of cones is amalgamated, whereby from 30 per cent to 35 per cent of the valuable metals is recovered. Concentration on vanners is the next step, the concentrate being shipped to smelters.

The combined vanner tailings run into steel vats, using Butters and Meins distributors. The vats are originally filled with water through which the sand settles, while the slime overflows.

FIG. 6.—KOMATA REEFS MILL

When a vat is full of sand it is drained and leached with cyanide solution. The slime is pumped to the large spitzkasten previously referred to, there being two sets of nine pyramidal boxes; each 6 ft. square and 6 ft. deep. Limewater is added to facilitate settling. The underflow from these spitzkasten passes to rectangular settling tanks, 20 ft. by 10 ft. area and 7 ft. deep, each having two pyramidal hoppers in the bottom, 10 ft. square and 7 ft. deep. The overflow from these passes in succession to two sets of flat-bottom circular vats to effect further settlement before flowing to waste.

Slime for agitation, consisting of water and ore in the ratio of 2:1, is drawn from the settling vats and pumped to tall agitators which, like those at the Waihi, have no central lift-pipe. When an agitator tank is filled within 18 in. of the top, the flow is diverted and the slime allowed to settle for an hour or more. The clear water is decanted, cyanide solution added to form a pulp of one part solids and one part solution, and agitation proceeds for 24 hours. Air is used at 40 lb. pressure. Filtration in a Moore fixed-frame type of filter completes the treatment of slime at this mill. At the present time the Talisman company has a new mill under construction, the operating costs of which are expected to show a considerable reduction in comparison with those of the mill described above.

Komata Reefs Mill

The view of the Komata Reefs mill, Fig. 6, is interesting as showing the first tall air-agitation tanks ever erected for the treatment of ore-slime. These are the two at the left, behind which are two others all resting on the elevated platform.

The other tanks at the right, with continuous sides resting on concrete foundations, were erected later. These agitators are equipped with central lift-pipes, which are an essential part of the original invention of Brown and McKen. Another important contribution to the mechanics of cyanidation originated with Mr. Brown, namely, the iron plate-and-rib liner for tube mills.

The practice at this mill conforms in some respects more nearly to modern ideas about handling slime. The ore is crushed in water and classified in spitzkasten, the sand being reground in tube mills. The tube mill discharge is classified in other spitzkasten, the sand passing to leaching vats, and the slime to Dorr continuous thickeners. The latter continuously discharge a pulp containing less than 40 per cent moisture, which is pumped to the agitators and mixed with cyanide solution to a consistency of about 65 per cent solution and 35 per cent solids. Intermittent charges are agitated for seven or eight days, after which the pulp is drawn off to a Dorr thickener which removes clear cyanide solution and gives a pulp containing about 45 per cent solution, which is finally displaced in a Moore "turnover" type vacuum filter.

Waihi-Paeroa Tailing Mill

The practice at this mill is a good example of what can be accomplished in re-treating tailings from other mills when favorable conditions exist. The various mills at Waihi, Karangahake and Waitakauri discharge tailings into the Ohinemuri River, which has a fall of about 20 ft. per mile to a point about 6 miles above its junction with the Waihi River. Here is a stretch of more nearly level country where the stream deposits its burden of sand, while the slime is carried on to sea. It has been estimated that the mills on the upper reaches of the river have crushed from 5,000,000 to 6,000,000 tons of ore, and have discharged this quantity of tailings into the stream. The sand has accumulated in the natural settling basin referred to; and an estimate of the quantity of such material deposited is about 2,000,000 tons. To this must be added the current annual contribution of the upper mills, amounting to about 500,000 tons of sand and slime.

The project of the Waihi-Paeroa Gold Extraction Company, Ltd., involved dredging this sand from the river bed, grinding in tube mills in cyanide solution, thickening, agitating and filtering the slime thus produced. This has been successfully carried out in a 500-ton mill.

The dredging machinery, consisting of oil engine, air compressor, centrifugal pump and air-lift, is mounted on a pontoon. The lift-pipe is telescopic, and can be lowered to any desired depth. The centrifugal pump is used to force water through a series of jets near the bottom of the air-lift to thin the sand to the desired consistency for pumping by compressed air. The sand is pumped into barges and towed to the wharf.

Charcoal and river sand are removed by treatment on vanners, after which the valuable residue is ground in tube mills working in a closed circuit with classifiers. The tube mill product is all finer than 150-mesh. This is elevated by two-stage tailing wheels to large settling cones from which the thickened pulp is discharged at a consistency of about 11 to 1. It is pumped to tall air-agitators which are without central lift-pipes, and agitated for forty-eight hours.

The Moore type of vacuum filter is used, the tanks being

circular and cone-bottomed. One tank is used for loading and one on either side of this for washing and discharging respectively. A disintegrator is placed in the bottom of the discharging tank, for the purpose of churning the caked slime with water before finally discharging it to waste.

Blackwater Mines Reduction Works

Stamping in cyanide solution is practiced at this mill, which is illustrated in Fig. 7. The view shows plainly the tall agitation tanks, dewatering cones, Moore filter and sand vats. The

FIG. 7.—CYANIDE MILL, BLACK WATER MINES

dewatering cones and Moore filter tanks are of wood; the agitators have no central lift-pipe.

The first separation of the stamp pulp into sand and slime is made in the leaching vats, the overflowing slime and solution being pumped back to a series of large wooden dewatering cones. The latter thicken the pulp to a consistency of about two to one, after which it is agitated. Vacuum filtration completes the slime treatment.

Summary

The characteristic features of New Zealand practice in handling slime may be summed up as follows: Crushing in water prevails at most of the mills. Intermittent or charge agitation is customary, the continuous method having been tried and abandoned on account of the tendency of the coarse solids to build up in the tanks. All New Zealand mills use the tall air-agitator of Brown and McKen, but without the central lift-pipe, except at the Komata Reefs mill, where the agitator was invented and first used. It is generally claimed that the use of the central tubes give no better results; and as thus apparently the only feature of the agitator covered by patent it is generally omitted. High air pressure, 40 lb. per square inch, is customary, being about double that used in America.

Tailing wheels still hold their own as elevators in New Zealand mills. The last to be erected are at the Waihi-Paeroa, where a two-stage lift is adopted. The Brown ribbed liner for tube mills, which is being more generally adopted in other countries, was originated in New Zealand, and is generally used there. The Moore filter has a strong hold, all the mills of any consequence using it. One of the peculiarities of construction of filter leaves is the substitution of corrugated sheet steel for cocoa matting in the center. It is claimed that this type of leaf filters just as well as the other, is lighter and dries more quickly; also that it is more readily cleaned if leaks occur in the outer canvas.

Denver, Col

Carbon Electrodes for Electrolytic Cells

By John Hårdén

A good deal of artificial carbon electrodes are to-day used for electrolytic work, and the subject of their manufacture is still rather important, although it may perhaps be right to say that the bulk of carbons made at present and more so in the future are used for electrothermal purposes. A few data regarding the "electrolytic carbons" may, therefore, be of some interest.

In the United States the graphitized electrode, first introduced on a larger scale by Dr. Acheson, whose name has rightly become famous in connection with this industry, has gained a well-deserved market. In Europe these electrodes have also obtained due recognition, but here the conditions are considerably different so that common amorphous electrodes are still to a considerable extent in use.

This may be explained by relating the writer's experience in some electrolytic works in Russia some years ago. These works produced on a large scale chlorine and caustic soda from ordinary sodium chloride obtained from the Black Sea and from the Caspian. Having been engaged previously as head of the testing department of a large carbon electrode factory, the writer was given ample opportunity to compare and to judge the particular "pro's and contra's" in question.

Since a heavy duty was levied on the finished article, it was found uneconomical to import the electrodes from abroad, and no factory was in existence in the country itself. The preparing of the raw material, however, is of great importance, as will be seen later. Therefore the ready prepared mass was obtained from a foreign carbon factory on the other side of the frontier, transshipped as raw material, consequently free of duty, and pressed and calcined into proper electrodes at the works. This realized a considerable saving and made the large outlay of a complete electrode plant with expensive machinery and large stock of materials unnecessary.

In spite of this, the cost of electrodes was a heavy toll on the works' budget. The cells consisted of an earthenware top in which seven round electrodes, about 4 inches in diameter by 2 feet 6 inches in length, were fastened. Diaphragms of asbestos separated the two compartments, anode and cathode room, and as the electrodes were worn off, the whole set of cells, six in each batch, had to be dismantled when repairs were to be made.

In order to lengthen the life of the cell, some graphitized electrodes were tried, with partial success as was expected. In those days, however, such electrodes imported from U. S. A. became very expensive, not only on account of their initial considerably higher price, but the exorbitant freight and unavoidable loss in breakage. It was generally found that the outlay for such electrodes, under the prevailing circumstances, was not in any way justified by their longer life, since the local labor was so inexpensive that it did not come into play, and the saving in material, although decidedly marked was not sufficient to compensate the other outlay.

This state of affairs is no doubt responsible for the fact that non-graphitized are still being used to a great extent, notwithstanding that the graphitized material is superior as regards actual wear and tear. In order, however, to test the matter more fully, the firm decided to graphitize its own electrodes on the spot, thereby utilizing a method worked out somewhat earlier by the author, and which differed in various respects from the Niagara practice. Some of its points have been briefly described in an article in *METALLURGICAL AND CHEMICAL ENGINEERING*, vol. IX, p. 130, March, 1911, headed "Some Electric Furnace Notes." A furnace was built and put into operation and after a few failures and alterations we succeeded in obtaining a continuous working, producing some 12 to 16 graphitized electrodes per day.

But even then, the economy was very problematic. Although the cost of power was not excessive, since it was produced by means of cheap local coal, the saving generally was not so great as at first expected. The electrodes prepared in this

way, though fully graphitized, showed a marked tendency to scale off in the bath, an experience, by the way, which has been since made also in electric furnace work, when the higher conductivity of the graphitized carbon has been made use of in order to increase the current density, thus decreasing the running costs of electrodes generally.

The graphite scales thrown off lodged in the bottom of the cell and clogged this up to such an extent, that it had to be opened and cleaned long before the electrodes were worn out, thus rendering the apparent saving illusive. This was due, to a great extent, probably to the fact that the material from which the electrodes were made was not quite suitable for this particular purpose; if a carbon factory proper had been connected with the works, it is quite possible that the fault may have been remedied to a greater extent. This problem of scaling off is one which the manufacturers of graphitized carbons should bear in mind; a material which, when graphitized may serve very well for one purpose may be quite unsuitable for another; in this case probably because every trace of the carbonaceous binder was thoroughly burnt out and converted into graphite as well as the main body, a fact which was fully shown by means of microphotographs, taken by the author and published in *Zeit. f. Electrochem.*, 1901, p. 324, and also by Sproesster in No. 71 of the same journal.

Large grains with adequate binding material, pressed under moderate force, which gives a very good result for furnace electrodes when used as amorphous electrodes, showed this scaling off in a marked degree when graphitized, although the porosity generally is much lessened. Finer grain, with less binder, stamped hard, calcined and graphitized, showed a better result in this respect, though the resistancy against the chemical action of the electrolyte is then generally lessened.

For the same reason it was also found that material which had been previously graphitized and then ground to suitable size, gave with an adequate binder of tar and high pressure as well as good calcination a comparatively better result. The economy of this working, however, was less satisfactory.

The Testing of the Electrodes for Electrolysis

The testing of the electrodes is of great importance, both for the manufacturer and the user. For the former, as it will tell him about the raw material and its preparation and also the subsequent manufacture so as to avoid complaints, etc.; for the latter to make sure that he has the right kind of material, since a fault may cost him a good deal if it is found out only when the cells have been built in. Generally, it should be emphasized that an electrode should be tested in the solution and under conditions as near as possible to those in actual use.

Preliminary, the following observations should be made:

- (1) Homogeneity and grain.
- (2) Absence of cracks and flaws.
- (3) Porosity and specific weight.
- (4) Contents of inert material.
- (5) Electric conductivity, and last but not least—
- (6) Resistivity to corrosion.

(1) Homogeneity and grain should give an idea of the uniformity of the raw material; if too fine and of a deep black luster, too much dust and "lampblack" material has been used. Such an electrode is likely to be less strong mechanically and will often cause larger lumps to drop off in the cells. A grey structure with light, shining points or globes indicate the presence of a large quantity of petroleum-coke, which if used in excess may behave similar to the former kind.

As a rule, the structure of a good, durable, amorphous electrode should be of even grain, not too fine, the grains being well and evenly united by the binder of a dark greyish color. Each particle of the mass should be thoroughly enveloped in a film of the cement or binder before pressing, and it is this part of the preparation of the raw material which calls for the utmost care and attention, and which, besides the choice of the material and the calcining, is the mainstay of the durability of the electrode.

Ingenious machines, the description of which space forbids,

have been invented and put into use to produce this effect, and money spent on this by the manufacturer is well invested.

(2) The absence of cracks and flaws is of course equally essential for the same reasons. These may be caused (and are usually caused) by inadequate treatment of the raw material, but also through false methods of calcining. The firing usually takes place in a gas-fired "ring" furnace, in which the electrodes are placed, embedded in coke dust, etc. If this packing is uneven, the electrode will "hang" and edge cracks are the result.

Such cracks are bad enough in electrodes for electrolytic work, since the increased resistance of the carbon may cause a poor distribution of the current and also cause the faulty electrode to drop off, but they are distinctly bad in the case of furnace electrodes, where a broken electrode may mean a whole smelt to be spoiled. Such occurrences are now-a-days rather rare, where proper "ring" kilns for calcining are employed, but a less scrupulous foreman may cause faulty products even with the best kilns.

A good, sound amorphous carbon should, when hanging free in a sling, and tapped with a steel bar, give a clear, distinct ring like a bar of hard cast iron, and endure nearly the same rough handling as such. A graphitized carbon again should give a deep "thud," yet clear and sound, be capable of polish by means of a brandishing iron and be soft enough to be cut with a knife, while the amorphous carbon is hard and should not permit cutting with other tools than the chisel and emery wheel.

(3) The porosity and specific weight are also both of importance. A certain amount of porosity is of advantage, as it will increase the active surface of the carbon; but if in excess, the bath liquid will enter the pores and cause a rapid development of gas which tends to break off small chips, especially at the less porous edges and thus shorten mechanically the life of the electrode. A good practice, gained by comparing a new carbon of unknown merit with a test piece of a well-known quality, whereby a medium strong magnifying glass should be used, will be found helpful. The pores should be even and not too marked, resembling those on a hard sugar loaf, the calcined binder causing the surface to appear slightly glazed.

The general way in which the specific gravity is determined may be shortly described.

A piece of the carbon, not too small, preferably cut out to regular size of a few cubic centimeters, is boiled in alcohol, dried in the oven, where it may cool and the weight is taken (*a*). Its volume (*v*) is then determined in a measure, the water is wiped off quick and the wet weight (*b*) is taken. The mean specific gravity is then $\frac{a}{b}$ and the real specific gravity is

$$\frac{a}{v - (b - a)}$$

It may also be determined by means of the method of suitable heavy liquids, such as a mixture of bromoform and chloroform of known specific gravity.¹

The relative specific gravity varies between 1.4 to 1.6 while the real specific gravity is generally between 1.6 to 1.8, and the porosity $\frac{100(a-b)}{a}$ is ranging from 11 to 22.

(4) With inert material is understood such contaminations which do not act as electrode material proper, but may be due to interior purification of the raw material. This is determined through ash-analysis, i.e., combustion in oxygen and air, whereby both the CO₂ evolved and the remaining ash should be weighed. Good carbons made from petroleum coke and lampblack have usually only about 0.3 to 0.5 per cent of ash, while anthracite electrodes may have 3 to 4 per cent.

Acheson graphite electrodes show as a rule a very low content of ash, due to the high temperature at which they have been treated. Electrodes for electrolysis ought not to have more than 2.5 to 3 per cent ash, while 4 to 5 per cent, as is sometimes found, is distinctly disadvantageous. The

carbons for electric furnace work should suit the conditions for which they are to be used, i.e., for carbide furnaces a content of 3-4 per cent lime is quite tolerable, for steel furnaces 1 to 3 per cent iron, etc., but the life of the electrode will suffer from a higher content of these substances.

The microscopic examination may also be of considerable use for determining the quality with a skilled observer, but it would carry us too far to enter further into this without the reproduction of the various sections. The author has taken a number of microphotographs of carbons manufactured in different ways and he may state as a general rule that the microphotograph will show clearly if rapid consumption of the carbons is due to insufficient calcination of the binder or if the main raw material was of an unsuitable nature. Again in this respect, the graphitized electrode gives a distinctly superior result, as the sections taken prove that practically all of the binder is converted into graphite carbon.

(5) The electric conductivity is naturally of considerable importance, for the more voltage we must apply to a cell, the greater is the dead cost of the electrolysis. That this is a weighty question is obvious, if we remember that a cell is usually operated with several thousands of amperes and a slight increase in resistance will soon run up the bill. This is also, though not to such a degree, of importance in furnace work, as may be clear from the following experience of the author.

A set of metallurgical furnaces was operated with carbons of 14 in. diameter at 4000 amp. The stumps were screwed on to the new electrodes by means of threaded plugs and graphite paste. A firm offered a brand of new carbons for which they claimed superior quality at a somewhat lower price than the usual cost of amorphous electrodes. The average resistance of a new carbon not in use was found to be within the proper limits, and a couple of the carbons were put into use as a test.

After a few runs it was found that the carbon scaled off in a remarkable way and one of the electrodes, having been jointed in the meantime, became red hot in the joint, in spite of the fact that the joining was made with special care and with the material specified by the maker. The voltage drop in a 5-ft. unjointed and in a 6-ft. jointed was taken and found to be 4.8 volts in the former and 6.9 volts in the latter at 4000 amp., consequently 19.2 kilowatts were wasted in the former and 27.6 kilowatts in the latter which, of course, made the use of these electrodes an impossibility, since the reduction in initial cost was in no way equal to the loss in power. It may be added that inductance and leakage was duly considered, in any respect it was of little importance, since the periodicity was fairly low, only 22.5 per cent.

The specific resistance is

$$\text{Sp. R.} = \frac{r q}{l}$$

where *r* is the measured resistance of a strip in ohms, *q* is the cross-section in square millimeters and *l* the length in meters. It ranges usually for amorphous carbons from 58 to 75, for graphitized electrodes from 6 to 12 and for charcoal electrodes up to 150.

As it is, of course, of great importance that the fastenings of the carbons in an electrolytic cell have as low resistance as possible, it is found advantageous to provide the ends of the carbon slabs with a good coating of graphite paste in all such cases where graphitized carbons cannot be used for one reason or other. The author prefers, where the conditions of the cell permits, to cast a shoe around the upper end of the carbon bar of a type of metal which will contract strongly over the carbon, yet be soft enough to avoid an undue strain on the bar. An alloy of lead, antimony, and bismuth in proportions tested for different brands of carbons has been found very suitable, and as only a thin coating is required, the expense is amply justified. Copper plating is usually found obnoxious, even if the nature of the electrolyte is such as to not corrode the copper, since it is found impossible to eliminate all traces of the acid of the copper bath from the pores of the carbon and the plating will invariably peel off and cause poor contact in time.

¹Z. f. El. Chem., 1901, p. 973.

(6) The resistivity to corrosion is the vital point in question, as has already been mentioned. If a carbon is used as anode in a cell, the carbon-block is invariably disintegrated, more or less, depending upon the nature of the carbon and also of the solution forming the electrolyte. Some of the products, in the case of an alkali cell are gaseous, some go into solution and the bulk is setting off as a slime. Oxygen-giving solutions are more active in this respect, but chlorine is also an enemy to the electrode.

If amorphous carbons are used, one may frequently find a product formed called mellogen, which may be characterized by the formula $C_{12}H_2O_4$, which is soluble in alkali and in concentrated sulphuric acid. This will be changed into mellithic acid ($C_{12}H_2O_{12}$) at ordinary temperatures. The same may be observed in using retort carbon, while graphitized electrodes² will form graphitic acid $C_7H_4O_5$.

The most reliable way of testing the carbons in this respect is to demand from the maker two or three pieces cut out from the electrodes he intends to deliver and subject these to electrolytic test under such conditions as those prevailing in an ordinary cell, i.e., in a salt solution for chlorine-alkali electrolysis, for instance.

The author used for factory testing the following arrangement: 6 to 12 cells consisting of alkali- and acid-proof enamelled cast-iron vessels were connected in series, the cathodes being sheet iron bent into suitable shape. The carbon anode was suspended in a chamber made of earthenware, provided with asbestos diaphragm and open at the bottom. The solution was 20 per cent sodium chloride, which was kept constant, both to concentration, volume and temperature. The current density was also held constantly at 0.1 ampere per square centimeter by means of meters and regulating device.

A clock was so arranged that a series magnet would permit the clock to go as long as the cells were in operation, but arrested the work automatically when the current was shut off from the cells; in this way an absolutely reliable time record of the duration of the test was obtainable.

The gases evolved in the anode chamber were sucked through a weighed potassium hydrate solution, in order to determine the quantity of carbonic acid produced.

The carbons were cut into regular shape and size, $3 \times 1 \times 10$ cm, brushed, boiled in water, dried in warm alcohol and hot air, and, after the connection lead had been cast on, carefully weighed. It was then immersed in the cell, a soft rubber packing being used to exclude leakage of gases.

The current was then turned on and allowed to act during a given time, usually 48 hours. The electrode was taken out at regular intervals of 12 hours, boiled in water and dried in alcohol and weighed as before. In this way a curve was plotted, showing the deterioration as it proceeded, and the life of the carbon could in this way be easily predicted, if compared with the curve of a standard electrode of well-known wearing quality.

It was very interesting to observe how in many cases the curve was at first very flat, showing a slight wear only, but as the test proceeded the curve rose rapidly, owing to the fact that the outer layers were more calcined than the inner, also showing greater porosity, whereby the carbon particles were thrown off more readily. By comparing the voltage required by the cell during the test one could very well foretell when it would be more economical to exchange the carbons, even if they were not worn down totally, similar to the critical point of a carbon filament lamp.

One might object that this test was more destructive than the actual conditions in a regular cell, and therefore not conclusive. This, however, is counteracted by the comparison with the standard carbon, tried before in actual use and from time to time submitted to a blank test in series with the new specimens to be tested. The variations observed were so slight, that during the $3\frac{1}{2}$ years the author used this method for determining the wearing quality of such carbons, the variations could

very well be neglected and the test was found sufficiently accurate for decision, both for manufacturing and ordering.

A few figures gathered by the author may serve to give an idea of the losses under above conditions: the figures are given in grams per 10 amperes per hour, 20 per cent salt solution and 0.1 ampere per square centimeter density.

1. Conradty	5.17
2. Le Carbon	2.80 (Graphitized)
3. Plania works	1.90 (special composition)
4. Schiff & Co. "X"	5.65
5. Retort Carbon	2.92
6. Acheson Graphite	1.06
7. Author's Graphite	2.02

As will be seen from the above, the graphitized electrode is generally superior to the ordinary carbon, but, as already stated, local conditions at the works may under circumstances be such, that one has to use ungraphitized electrodes on account of costs, etc.

The specimen No. 3 shows that it is also possible to produce an amorphous carbon with a wearing quality practically as good as the graphitized one, but it is only just to add, that, owing to its special nature, the price of this was almost the same as a graphitized one. Apart from this, the specific resistance was about eight times higher, and the material very hard and brittle, wherefore it could not be recommended as a good substitute for the graphitized brand.

It is quite clear from the above, that the judging of the merits of a good carbon for electrolytic work requires a good deal of consideration and patience, if a fully economical working result is to be arrived at. It should be borne in mind that the general points set forth above do not by any means exhaust the subject of the testing, but they will serve to give an idea of the faults and merits to bear in view.

Luton, England.

The Fourth International Congress on School Hygiene will be held in Buffalo, N. Y., from Aug. 25 to 30, 1913, under the patronage of Woodrow Wilson, President of the United States. Delegates will attend from all the leading nations, from every college and university of note in this country, and from various other educational, scientific, medical and hygienic institutions and organizations. The congress is further open to all persons interested in school hygiene. Membership may be secured on the payment of a \$5 fee. Applications should be sent to Dr. Thomas A. Storey, College of the City of New York, New York City.

The American Metal Company, of New York City, has purchased 2500 acres of Pittsburgh coal lands and 350 of surface land at Purgettstown. On this surface land the company will commence to build a zinc and sulphuric acid plant. A subsidiary company, known as the American Zinc & Chemical Company, is being organized with a Pennsylvania charter to operate the new plant, and Mr. N. L. Heinz, of LaSalle, Ill., one of the best-known zinc and sulphuric acid experts in the United States, will be the general manager and has been made a member of the board of directors. What is known as a one-unit plant will be erected and will have a capacity for producing 40,000 tons of sulphuric acid and 20,000 tons of zinc annually. The plant will be so designed that it can be enlarged rapidly, and it is the intention to build additional units until the annual capacity amounts to three or four times the original.

A shaft will be sunk and coal mining operations will be commenced coincident with the opening of the plant. The initial investment in this new plant will be not less than \$2,000,000, and it is expected that when the entire plant is completed and in full operation, which will probably be within three years, it will represent an investment of approximately \$5,000,000.

The new plant will give employment to 500 men at the start and as the plant is enlarged this number will be increased until about 1500 men will be employed.

A Modification of the Jäger Method of Gas Analysis

By S. H. Worrell

In the November, 1911, number of METALLURGICAL AND CHEMICAL ENGINEERING, there was an article on a simple method of determining methane in producer gas and enriched water gas. The method was that made use of in ordinary combustion analysis of carbon compounds; namely, the use of copper oxide as a source of oxygen. The method is as old as Fresenius, of course, who absorbed the products of combustion and weighed them. In the article just referred to I made the statement that a fairly thorough search of the chemical journals failed to reveal anything published on the subject. I might have added also that the method was not to be found in any text book on the subject of gas analysis that is at hand in our library. Shortly after the article appeared, in looking up another reference, I found that E. Jäger had made use of the method and published it in *Journal für Gasbeleuchtung* in 1898. However, he went a step further, and by first heating the tube containing copper oxide to 250 deg. C., he removed the hydrogen, and then by igniting to redness burned the methane. His method in a modified form was at once put to use in this laboratory.

It was difficult to understand at first why a method so simple and seemingly so meritorious should not be in more general use or at least have found a place in textbooks on the subject of gas analysis. The reason is probably twofold. In the first place, Jäger's method of placing the KOH pipette beyond the copper oxide tube may be a source of error as will be shown later, and then the method of standardizing is tedious.

Unsatisfactory Methods for Carbon Monoxide and Hydrogen

In gas analysis, the absorption of carbon dioxide with KOH, and thereby the determination of its percentage, is a simple matter. The same is true with reference to the determination of the illuminants (unsaturated compounds) with bromine water, and oxygen with stick phosphorus. However, the absorption of CO with cuprous chloride, and hydrogen with palladium tube is sometimes less successful. At least the results obtained in the absorption of hydrogen with the palladium tube were never very satisfactory in the work in this laboratory extending over quite a number of analyses of a series of coal gas samples. Burning both the hydrogen and methane together was resorted to for awhile; the loss in volume being hydrogen which when burned condenses to water. But this method is open to the objection that there is no check on the carbon monoxide absorption with cuprous chloride; for, the CO present, if there is any, is burned to carbon dioxide and is absorbed and measured along with that due to methane. Furthermore, if there is any ethane present, which is possible, it increases the residue in volume when burned and thus decreases the apparent percentage of hydrogen. However, with Jäger's method, the hydrogen is first removed. Then when the residue from the hydrogen is burned, the increase if any in volume is due to ethane. In this way the ethane can readily be determined.

Of course no distinction is made in this case between ethane and any higher member of the series, which if present would be measured as ethane.

In using Jäger's method, a pipette containing water slightly acid with sulphuric acid, was always used instead of KOH as he directs. It was soon observed that the residue left after burning out the hydrogen at 250 deg. C., frequently contained a small quantity of carbon dioxide. At first it was thought that this small quantity of CO₂ was due to a partial combustion of methane, caused perhaps by its reacting with a small quantity of copper oxide dust that might be present, a very high temperature perhaps not being necessary to bring this about. However, prolonged heating at 250 deg. C., and repeatedly passing the gas did not cause the formation of

more carbon dioxide. As a matter of fact, this carbon dioxide when present was due to the burning of the small residue of carbon monoxide which had failed of absorption with the cuprous chloride, either through lack of thorough shaking or too weak a solution.

As a result of this observation, the cuprous chloride pipette has been discarded entirely, and after removing the oxygen with stick phosphorus, the procedure is simply to burn the hydrogen to water and the total of the carbon monoxide to carbon dioxide in one operation at a temperature of 250 deg. The loss in volume is the percentage of hydrogen present. The CO₂ formed is then absorbed by passing into KOH and the loss in volume is the carbon monoxide that was pres-

FIG. 1.—APPARATUS FOR GAS ANALYSIS

ent. The copper oxide is then heated to redness and the residual gas passed. The volume of gas is noted before and after burning. If there is an increase in volume it is due to ethane, and one half this increase is the percentage of ethane present. The total carbon dioxide formed is then absorbed and the residue noted. The loss in volume, accounting for the ethane first, is the percentage of methane present. The residue is the percentage of nitrogen direct.

Description of Apparatus

There follows a description of the apparatus necessary and a detailed statement of the method of using it with the precautions to be taken.

For the method in detail, reference is made to the accompanying illustration. All glass connections are of capillary tubing and the rubber should be thick-walled, tight-fitting. Referring to Fig. 1:

- a—Semi-permanently attached KOH pipette (500 gms. to the liter).
- b—Two-way stopcock.
- c—Gas burette.
- d—Cradlock burner for convenience. Any burner would do of course.
- e—Asbestos board, 1 1/2 in. in thickness, solid.
- e'—Asbestos board, 1 1/2 in. in thickness, with a hole for a thermometer.
- f—A 4-in. asbestos air bath (Eimer & Amend Catalogue No. 2373).
- g—Silica tube, 1/4 in. bore, 7 in. long.

h—Pipette filled with water, slightly acid with sulphuric acid.

i—One-way stopcock.

j—Leveling bulb filled with 1% to 2% sulphuric acid.

Method of Procedure

The solution of KOH in *a* having previously been drawn over nearly to *b*, the stopcock is closed to *a* and opened to the air. Before the portion of the apparatus shown from *d* to *h* is placed in position, the burette is filled with gas to be analysed until the water sinks about one inch below the 100 cc. mark. The stopcock *b* is then closed and the leveling bulb *j* raised until the gas under pressure has a volume of 100 cc. The stopcock *i* is then closed and *b* opened, whereby the gas is brought under atmospheric pressure and exactly 100 cc. has been taken. The gas is then allowed to pass into *a*, when its carbon dioxide is removed. The water in the burette is now caused to flow out to the air until the entire system including the connection of capillary tubing is filled with water. The bromine pipette containing water saturated with bromine to which a few crystals of KBr have been added is then attached on the right. The gas, returned from *a* to *c*, and back and forth a few times if necessary, is measured by bringing the liquid in the leveling bulb *j* to a level with the water in the burette. Stopcock *i* is closed and the burette is read. The loss in volume is the percentage of carbon dioxide present.

The gas is then passed back and forth from *c* to the bromine pipette until bromine fumes are distinctly visible in the gas on returning to *c*. It is then passed into *a* to remove these fumes and upon being brought back to *c* is measured. The loss in volume is the percentage of "illuminants" (unsaturated carbon compounds) that were present.

The phosphorus bulb is then substituted for the bromine bulb and the oxygen determined in a similar manner; that is, by loss in volume.

The phosphorus bulb is then substituted for the bromine bulb and the oxygen determined in a similar manner; that is, by loss in volume.

Precautionary Measures

The apparatus as shown in the illustration is then placed in position. Care must be taken to have the right hand opening of the two-way stopcock *b*, as well as the capillary tubing leading from it, entirely free of KOH solution. In fact, *not one drop of KOH should ever be allowed to enter the burette* if it is possible to avoid it, for the reason that one drop can absorb many times its volume of CO_2 , causing an error in the hydrogen determination. If any KOH has entered, the gas should be passed into *a* after the oxygen is determined, and the passage way to the air thoroughly washed with the acid solution in *c* and *j* until all KOH is removed or neutralized.

The apparatus having been placed in position as shown, the air line on the capillary tube of *h* is noted. With a little care it can always be brought to the same place. The burner is then lighted and turned down until the bottom of the board *c* glows in one spot in the center from 1 to 2 inches in width. This will generally be found sufficient to bring the temperature of the air in the bath to 250 deg. C. which is the required temperature; from 250 to 260 deg. is sufficient. The silica tube in the air bath is filled in its central portion, about 4 in., with copper oxide, "wire form," crushed until it will pass a 20-mesh screen. The dust formed in crushing should be screened out and none passing 80-mesh should be placed in the tube since it clogs the passage of the gas. The remainder of the tube is filled with an asbestos fiber plug, about one-half inch on each side of the oxide, and then glass wool to each end of the tube. The glass wool is not necessary, except to make the air content smaller, and to help retard the passage of the water if it should by accident be allowed to enter the silica tube on either side. Care should be taken *not to pack* the copper oxide or it will expand on heating and crack the tubing. On the other hand it should fill the tubing entirely if possible, to prevent an empty passage along the top of the

tube, and so permit the gas to pass without coming into intimate contact with the copper oxide. A simple way to accomplish this is to place one plug of asbestos in position, then pour in the oxide and tap it gently with the finger to settle it. Then the other plug can be gently pushed into place. The proper place can be seen by holding the tube to the light.

Advantage of Silica Tube

In the former article alluded to above, a hard glass tube was recommended. It was soon discarded in this laboratory for the silica tube which does not bend on heating repeatedly, being more refractory; and, what is of more importance, it does not break if water is allowed to enter it from either side or is condensed from the water formed in combustion. The rubber tube connections to the capillary elbows at either end are of thick-wall "antimony" tubing. No difficulty is experienced from this tubing being burned, as it is protected by the asbestos air bath, through the walls of which the silica tube passes by means of two holes on opposite sides, just large enough to admit the tube and so placed that the center of the tube is about the center of the bath.

The temperature of the air bath having risen to from 250 to 260 deg. C. as shown by the thermometer, the leveling bulb *j* is placed on a shelf above the level of *f* and the cock *i* opened slightly to allow the gas to pass slowly through *g*. It must be passed back and forth until it no longer loses in volume. This means that it will have to pass through the silica tube six to eight times. Then, the light being extinguished, and the thermometer and *e* being removed, the apparatus soon cools to the temperature of the room. Then the gas is returned entirely to *c* until the water rises in the capillary tube of *h* to the former air line. The cock is then closed and the loss in volume noted. This loss in volume is the hydrogen present in the gas plus the oxygen of the air in the silica tube. All this oxygen has been used up of course. This volume of oxygen has to be subtracted from the loss in volume due to the hydrogen burning, and the difference is the percentage of hydrogen in the gas. (A simple way of determining the air volume of the silica tube or rather of its oxygen content will be given further on.) The residual gas is then passed into bulb *a* and the carbon dioxide formed by the combustion of the CO while heating to 250 deg. is then measured directly by the loss in volume due to the absorption of the carbon dioxide formed. To accomplish this thoroughly, the residue in *c* after being deprived of its CO_2 content is again passed through the silica tube, which of course contains CO_2 , and then the whole is again passed into *a*. By repeating this fractional removal three or four times, the CO_2 is reduced to an amount too small to be measured.

The reaction will be found to be complete at the temperature mentioned, provided the gas has been passed a sufficient number of times to burn the hydrogen completely. This can easily be determined as noted above, by passing it back and forth until it no longer loses in volume.

The asbestos board *e* is now removed, the burner again lighted and the tube heated to redness. It may be found necessary to place a single sheet of iron-wire gauze (the sort usually placed under beakers) on top of the bath to heat the tube sufficiently. But this is to be avoided if possible because it may cause heat enough to scorch the rubber connections.

The gas should be passed back and forth about the same number of times as was found necessary in the case of the hydrogen, but in this case can be passed much faster. The light is extinguished, the apparatus allowed to cool and the volume noted. It should be the same as before burning, or at least no less. If less, it shows that the hydrogen and possibly the CO were not completely burned, or that KOH was allowed to enter the burette and up into the capillary tube leading to the silica tube. Any increase in volume is due to ethane or a higher member of the series. This increase in volume, if due to ethane alone, may be read at once as the percentage of ethane. The gas is again passed into *a*, the CO_2 removed and the residue measured. The loss in volume is the percentage of

methane if there was no ethane. If ethane was present, then to determine the amount of methane, the percentage of ethane is doubled and subtracted from the total amount of carbon dioxide formed. For example suppose a mixture of the following gases in the residue: 8cc. of nitrogen, 20cc. of methane and 7cc. ethane, with a total volume of 35cc. Upon burning, the nitrogen, of course, is unaffected; the methane burns to CO_2 but has the same volume as before, but ethane doubles its volume on burning. The total volume will be 42cc.: 42-35 gives 7, the percentage of methane. When passed into KOH, the loss in volume will be 34cc.: 34 less 14 (double the percentage of ethane) gives 20, the percentage of methane. In removing the carbon dioxide, the same fractional method has to be resorted to as in the case of the carbon monoxide determination mentioned above. The sum of the various constituents determined thus far, is subtracted from 100 and the residue is nitrogen; or, the residue after removing the last of the carbon dioxide is the nitrogen percentage when the oxygen content of the silica tube has been added to it.

Correction for Oxygen in Air in Silica Tube

To "standardize" the silica tube and all that portion of the apparatus between *b* and the air line in *h*, the following procedure will be found convenient: Take any gas, such as average city water-gas or coal-gas, known to contain methane to the extent of say 5%, but no ethane, (no sample of gas has been analyzed in this laboratory in the past year that contained more than a "trace" of ethane) and remove the carbon monoxide and hydrogen by prolonged heating at 250 deg. as outlined above. The residue of methane and nitrogen is passed into *a*. The bulb *h* is removed, the burner again lighted, and the cuprous oxide and copper are again oxidized to black oxide of copper by repeatedly passing air in and out. The apparatus is then allowed to cool to the temperature of the room again, and air is once more passed in and out to be sure that the silica tube contains air only. The bulb *h* is then attached as before and the residue of methane and nitrogen burned as outlined above, by passing the gas back and forth two to four times. It is then allowed to cool, returned to the burette and the loss in volume carefully noted. This loss in volume is that due to the oxygen of the air content of the silica tube and accessories in place. This then is the amount to be deducted from the hydrogen percentage and added to the residual nitrogen to determine the percentage of nitrogen. The copper oxide in the silica tube can be reoxidized and used over and over again by passing the air as just described. After it has been used many times, however, it becomes more or less solid on the bottom. It then has to be punched out or dissolved out with acid and renewed. Incomplete combustion of the hydrogen on repeatedly passing it through, marks the stage when renewal is necessary.

Comparative Results

Following are the results obtained in a number of analyses by this method alone, and when combined with the cuprous chloride method.

Gas No. 1.			
1st sample		2nd sample	
CO removed with CuCl	4.6	CO removed with CuO only.....	14.0
CO removed with CuO	9.6		
14.2			
Gas No. 2.			
1st sample		2nd sample	
CO removed with CuCl	11.2	CO removed with CuO only.....	21.9
CO removed with CuO	10.6		
21.8			
Gas No. 3.			
1st sample		2nd sample	
All CO removed by CuO	16.8	All CO removed by CuO	17.00
Gas No. 4.			
1st sample		2nd sample	
All CO removed by CuO	15.5	All CO removed by CuCl	15.0
Gas No. 5.			
1st sample		2nd sample	
Carbon dioxide	0.2	0.2	
Hydrogen	2.0	2.0	
Oxygen	1.4	1.3	
Hydrogen	45.1	45.1	
Carbon monoxide	19.3	19.4	
Methane	24.4	24.6	
Residue	7.6	7.4	

The results given under No. 5 are those obtained in the course of the analysis, without applying the correction for the oxygen in the silica tube. To do this and obtain the correct results, 1.3 must be taken from the hydrogen in each case and added to the nitrogen.

In conclusion, attention may be called to the fact that in the Jäger method as outlined in the reference, if the CO was not completely removed it would place an error on the hydrogen due to the use of a KOH pipette where bulb *j* is placed in the accompanying illustration. The method of calibrating the silica tube as outlined is simple and accurate.

It may be that the determination of carbon monoxide by this method has already been done by someone else, but if so I have not seen its publication. At any rate, it has not found its way into the various textbooks on gas analysis. After repeatedly experimenting with this method for the past two years, the writer has a decided preference for the method as outlined above over the cuprous chloride, palladium oxide and explosion method, both from the standpoint of accuracy and also of convenience.

Chemical Laboratory of the Bureau of Economic Geology and Technology, University of Texas, Austin.

Utilization of Wood Waste—III STEAM DISTILLATION

By John E. Teeple, Ph.D.

The distillation of wood waste with steam, to recover turpentine and pine oil was at one time quite an industry, and what is more there were certain periods in its history when it was fairly profitable. The rapid development began about 1902 and reached its maximum in 1910 when a very considerable number of plants were in operation. Almost every plant operating during 1910 was able to show a profit for that year and the first few months of 1911. The fall in price of turpentine since then has made the business unprofitable. There is not today a single plant operating by steam distillation alone, excepting where its raw material is sawmill waste, and there are

FIG. 1.—STEAM DISTILLATION PLANT FOR RECOVERY OF TURPENTINE AND PINE OIL

only one or two of these. Since it is an industry that has completed its life course in that form, we can sketch its history with safety.

The process of extracting volatile products from pine wood with steam either saturated or superheated and with either excess pressure or reduced pressure, was patented in 1864 and 1865 by Hull, Leffler, and Emery, and has been repeatedly patented since in its various phases. It apparently did not become a profitable industry, however, until soon after 1900 when turpentine began to stay uniformly above 50 cents per gallon at Savannah.

Then the Krug patent was exploited to a considerable extent in Georgia and Florida. The novel idea of the Krug patent was two outlet pipes, one to remove the turpentine and pine oil, and another to remove the products of destructive distillation. The retort used was the regular horizontal type of hardwood distillation retort such as is commonly used in Pennsylvania

and southern New York. Experience showed that the second outlet for destructive distillation products which was the prime feature of the Krug patent was useless because with this system the plants never proceeded far enough to get destructive distillation products.

Nevertheless, several plants were installed using the general type of hardwood retort with only one outlet. Many improvements in methods of handling the wood, systems of conveyors, systems of discharging, apparatus to empty the retorts, convenient bins and chutes for filling them, enabled some of these plants to continue operating for several years. In this system the wood was brought in usually in 4-ft. lengths, and passed through an edging grinder, commonly known as a hog, to reduce it to fair-sized chips and later in many cases shredders were installed. These, with the engines, retorts, condensers and still house equipment were the largest items of cost.

Another type of retort used was a vertical one holding from

FIG. 2.—LIGHT WOOD IN THE WOODYARD OF A STEAM DISTILLATION PLANT

one to three cords. In some cases the steam entered at the bottom and passed upward through the wood. In other cases it entered at the top and passed downward. Each of these types of retorts variously patented by Gardiner, Acheson and Snell, were exploited to a considerable extent, especially in Florida. The chief differences were in the direction of passing the steam, modes of agitating and discharging chips, and variation in type of the lower door. All used saturated steam without more than 20 lb. or 25 lb. pressure.

In addition to the horizontal and vertical retorts another variety was set obliquely, consisting of a cylinder holding less than one-half cord set at an angle of about 60 deg., charging at the top and discharging at the bottom. Two plants of this type were installed in Florida.

Another type which was exploited to a considerable extent was the Bethune system, being a type of vertical retort using superheated steam. Some five or six plants were installed from North Carolina to Florida, but the superheaters usually failed on account of insufficient control and were gradually abandoned.

Still another type was the revolving retort suspended on trunnions, the steam entering through one trunnion and the volatile products passing out through the other. This type seemed to offer certain advantages for charging and discharging, and for agitating the product during extracting. The retorts were sometimes cylindrical or frustum shape, and sometimes spherical. This type of retort offers a curious example of the recurrence of ideas and of the failure to profit by experience and other men's work. Some eight or nine years ago when this idea of a revolving retort was first brought to the writer's attention it seemed to offer enough advantages over other methods at that time in use to warrant a fair trial, so two retorts were designed and installed in a plant in Mississippi.

Just about the time these were ready to operate, a patent was granted to a man in Georgia who apparently had the same idea, although as far as I could learn he never progressed far

enough to install an apparatus to try out his idea. A few months later the writer was called to inspect a plant in Georgia and found there the same general type of retort in operation. It differed somewhat in shape and construction, but the idea was there as in the others. A few years later the same type of retort was called to his attention at a plant in Louisiana, and within the last three months an inspection of another plant near the Texas border revealed our old friend only recently installed, and ready to operate.

In all these cases the newer plant had apparently been installed without any knowledge of the previous ones, and in each case the previous methods had been practically abandoned after careful study of them before the new ones were built. This is simply one of the many cases that might be cited of a continual repetition of errors resulting in financial loss, and in each case the loss might have been wholly avoided by careful study of what had been done before and what data was available regarding that type of installation.

All these installations mentioned had the retort in the shape of a cylinder or frustum of a cone hung on trunnions. Two installations were also made in Georgia of spherical retorts hung on trunnions. These retorts had a much larger capacity than the cylindrical ones, but the method of operation was the same.

When any of these types of retort was used, the method of extraction removed only the turpentine and pine oil. The chipped refuse when discharged from the retorts was very similar in appearance to the original raw material. A portion of it was used for fuel to run the plant, the remainder being sold either locally or at a distance to railroad shops, tug boats or firms requiring fuel for power. As the wood was very resinous the waste made an excellent fuel when the furnaces were properly equipped to use it.

Steam distillation plants required large quantities of steam for power to run the hogs, shredders and conveyors, and for extraction in the retorts, but their waste materials always furnished them more than sufficient fuel, and from one-half to two-thirds of the total extracted wood was available for sale, provided there was a market.

Many attempts were made to extract further products from this waste in the same retort. In one plant in Florida the retorts were built to stand 80 or 100 lb. pressure, with the idea that steam under this pressure would melt the rosin and allow it to be collected at the bottom of the retort. In another, superheated steam was used on the assumption that the wood would be charred and destructive distillation products obtained, but all of these methods failed in actual practice because of the physical condition of the wood. The very large amount of surface exposed prevented an efficient draining and collection of rosin or tar.

Regardless of the type of retort, all of the steam distillation plants finally came to about the same method of operation. The wood was usually brought in in 4-ft. lengths, as stated, but in one case the hog was large enough to receive full-sized logs, and in some cases stumps were used. The wood cost variously from \$1.75 to \$4.50 per cord, probably averaging about \$2.75.

When the wood was hogged, and sometimes shredded, it was placed in the retorts and subjected to a saturated steam extraction. Experience showed that the best results were obtained by varying the pressure with the amount of volatile products distilling.

At the outset the distillation proceeds normally with little or no pressure. When the volatile products decrease if the pressure is raised to 10 or 15 lb. the steam penetrates further into the wood, then when the pressure is decreased the steam and volatile products come out of the chips together and a normal flow of distillate proceeds. This is repeated several times until the extraction is as complete as conditions at that plant warrant.

The maximum pressure usually does not exceed 25 lb. and the time of extraction varies from three hours to six or seven hours, usually not more than four. The crude distillate varies from 10 to 17 gal. per cord, depending on the quality of the wood. Individual cords often give as high as 20 or 25 gal.

but 14 or 15 gal. per cord of crude distillate is considered a very good average unless the wood is especially well selected. The crude distillate separated from the water is then redistilled in stills, with or without fractioning columns, and separated into two marketable products, turpentine and pine oil.

Steam distillation plants deserve the credit for being the first ones to place on the market large quantities of well-refined turpentine and pine oil of a uniform quality and to develop a large market for those products. Steam distillation will be continued probably as a part of other processes, but not as a sole means of utilizing wood, excepting in the case of sawmill waste, which will be discussed in a later article.

It must be said in favor of the steam distillation plants that most of them were built on the very clear understanding that they were not complete processes. The owners in many cases recognized that there was a comparatively small margin in the recovery of turpentine and pine oil alone, even under

FIG. 3.—FEEDING THE HOG

favorable conditions, but the recovery of further products seemed reasonably certain on further investigation.

This recovery did not progress as fast as most of them hoped. Attempts at destructive distillation of the residue revealed many obstacles. Methods of extraction were a long while in being worked out and the ones of these in successful operation will be discussed in another article.

Methods of heating the chipped residue from the outside failed because it was very difficult to make heat penetrate through the mass of sawdust or chips easily, and because when it did penetrate the resin or tar clung to the chips so closely that it could not be recovered to advantage. Methods of incomplete combustion of the residue by burning a portion of it in order to distil the remainder gave some results in small-scale retorts holding a half cord or more, and this might possibly be worked out. A fair grade of tar and tar oil can be produced in this way.

The steam distillation plants were of varying capacity, from 5 to 10 cords per day up to 80 cords per day, and represented investments of from \$10,000 to \$200,000. Where the proper location was selected and construction was good, the plants will probably be permanent, after making the necessary additions. Where poor judgment was used in selection of location or where the construction was not substantial, the plants will be very nearly a total loss. Many have already been dismantled or transformed into other types of plants or had additions made to bring up the total production per cord of wood to a profitable basis.

The difficulty of the steam distillation plants as such was a simple one of revenue. Given a cost of wood of, say, \$3 per cord and manufacturing cost of \$1 to \$2, and taxes, insurance, depreciation, interest and overhead charges of, say, another \$1, besides the cost of packages and selling, their operation was entirely dependent on the price of turpentine. When turpentine was high so that their products brought from \$7 to \$11 or \$12 per cord, they were happy. If their products bring only \$4 they are out of business, and this is their present condition.

Comments on the Report of the Investigation of the United States Patent Office.

By L. H. Baekeland

Whoever is interested in the patent situation of this country should make it his duty to read the unusually interesting publication¹ just issued by the U. S. Government, which covers 624 closely printed pages.

On August 21, 1912, the following joint resolution was passed:

"That the President of the United States be, and he is hereby, requested to cause the accountants and experts from official and private life now or hereafter employed in the inquiry into methods of transacting the public business of the Government in the several executive departments and other executive Government establishments, known as the Commission on Economy and Efficiency, to investigate fully and carefully the administration of the Patent Office with a view of determining whether or not the present methods, personnel, equipment, and building of said office are adequate for the performance of its functions, taking into consideration the present character and volume of business, and also such increase in complexity or volume as may reasonably be expected in the future, and to ascertain and recommend specifically to Congress not later than December 10, 1912, what changes in law, what increases in appropriations, and what additional building accommodations, may be necessary to enable the Patent Office to discharge its functions in a thoroughly efficient and economical manner, and to what extent any expenditures which may be recommended can be met by increases of Patent Office fees.

"All expense incurred in carrying out the purposes of this resolution shall be paid out of any funds in the Treasury of the United States not otherwise appropriated, and the sum necessary for said purposes is hereby appropriated: PROVIDED, That the total expense authorized by this resolution shall not exceed the sum of \$10,000."

The report as presented is signed by Frederick A. Cleveland, Walter W. Warwick, and Merritt O. Chance, Commissioners on Economy and Efficiency.

This interesting report enters into the many ramifications of our patent system, shows up its defects and indicates in a practical way possible methods of improvement.

An enormous amount of precise information has been collected by the above-mentioned commission, but what is more impressive is that all this has been accomplished with the expenditure of such a comparatively small sum of money as \$10,000, and the report should have been prepared and published three months and a half after the resolution was approved. This in itself is a worthy example of "economy and efficiency."

With these data at hand, in addition with the report of the hearings on the Oldfield Bill (see report No. 1161, to accompany H. R. 2347, by Hon. W. A. Oldfield, House of Representatives, 62nd Congress, 2d Session), any future commission for the revision of our patent system will have its work much simplified.

Certain defects in the handling of the personnel of the patent office are pointed out: for instance, it is mentioned that there are no efficiency records for the examining force and that for many years there have been no examinations for the purpose of determining the efficiency of examiners and regulating their promotions and reductions. Such efficiency records, in conjunction with an examination system, would tend to encourage all employees to do their best work and would make adequate salaries a real and lasting benefit to the service.

Emphatic stress is laid on the unsuitability of the present Patent Office.

"In the preliminary survey preceding the investigation the commission was impressed with the idea that the building accommodations for the Patent Office are so inadequate as to

¹62d Congress, 3d Session, House of Representatives, Document No. 1110. Report of the Investigation of the United States Patent Office, made by the President's Commission on Economy and Efficiency, Washington, December 6, 1912.

render extremely difficult any substantial improvement in the work of the office. This impression has been changed as a result of the investigation until it has become a settled conviction that any permanent improvement in the quantity and quality of work done by the office, if done at a reasonable cost, must wait upon provision being made for adequate office accommodations for the force of more than 900 people employed in the Patent Office."

It is a hopeful sign that the Bulkley Bill (H. R., 28,193, 62d Congress, 3d Session) should already have taken up this matter, and intends to provide a \$4,000,000 fireproof building. It is questionable, however, whether this sum of money will be sufficient for the purpose. When we take in consideration that the Patent Office has now an accumulated surplus of \$7,000,000 over all its expenses, there is no reason why this surplus should not be used for providing a suitable building, and the equipment that goes with it.

Through the courtesy of the authorities of the German Patent Office, I have recently been enabled to inspect that magnificent patent office building in Berlin, and its operation. I have been more than ever impressed with the fact how antiquated and inadequate our Washington Patent Office equipment has become in view of the enormously increased development of our country.

As to the needed changes in our patent laws, the remark is made that the present law is substantially the same as the act of 1836. There is a significant allusion to the conservatism of lawyers and their opposition against any changes in procedure.

"No change, however much it may be needed to keep pace with changed conditions, can be made without vigorous opposition due to a large extent to that inherent prejudice against disturbing the daily routine life and the inconvenience of adapting one's mind to a new course of action. . . . Recommendations made by the present Commissioner of Patents for the amendment of laws to effect what he considers are improvements in the methods of the office and to expedite its work are opposed by those who do not agree with him as to the wisdom of the changes as well as by those whose financial interests would be affected unfavorably. . . . the commission is convinced that any proposed change in the patent law and almost any proposed change in the methods of procedure in the Patent Office will arouse opposition from some persons interested in securing patents."

This statement is very well corroborated by the answers to the list of questions sent out by the Economy Commission to members of the bar, inventors and others interested in matters before the Patent Office. More than 400 replies were received. On most questions there was a considerable divergency of opinion.

But even here it is significant that on question No. 24, relative to the desirability of creating one single Court of Patent Appeals, the answers were practically all affirmative and only a few opposed.

Questions 1, 2, and 3 asking opinions as to the advisability of abolishing one of the two appeals in the office and creating one appeal board of five or six members were answered in the affirmative in about 80 per cent of the replies. The direct negative to these questions was less than 20 per cent. The trend of the opinions expressed lies decidedly toward a single appeal to a board in the office, particular stress being laid on the importance of having the work of the primary examiner performed in a thorough and capable manner. The great majority of answers opposed the sitting of the commissioner, the assistant commissioners, or any administrative officer on this board, the idea being expressed that the commissioner should be left free to devote his time to purely administrative duties.

Answering question No. 14 "to what extent should the decision on such appeal operate as a final adjudication of patentability," a small number answered that the decision should be final, and a few that it should not be final. Some favored it being final only as to adverse decisions. Other suggestions were: It should be final, but not as against newly discovered

prior art, in case of litigation under the patent; decision of the Patent Office in interference cases to be final and only to be opened in court upon new evidence found, as the proceedings are far less expensive in the office than in the courts.

Chapter 4 is devoted entirely to an examination of our cumbersome and time-robbing system of interference. The commissioners conclude that it would be better not to make any important changes in our present interference procedure. They seem to overlook the fact that our interference system, as it stands today, hardly protects the "first" inventor if the latter does not possess the abundant cash required to defend his rights against wealthy opponents. Furthermore, a good patent system should be devised in the interest of the nation, the public at large, and not for the limited individual benefit of some inventor or another.

The essence of good patent law is to induce inventors to disclose their invention as promptly as possible, so that the public may have the early benefit of such publication. Our interference proceedings, in conjunction with other defects in our methods of allowing patents, encourage systematic delay in the publication of patents; in reality, a premium is now put on such delays.

All this would be much simpler if in all interference cases priority were allowed to the independent inventor who has filed first his patent, provided he has not copied nor stolen the invention from others.

The German law allows an almost absolute claim to priority to the earlier applicant. This system, therefore, has the great advantage of simplicity over the system in practice in the United States, but it may become a source of injustice in case the latter applicant is really the earlier inventor. However, the latter applicant has only himself to blame if he does not file his application in due time, instead of doing as is now the case, and purposely postpones filing his claims under the immunity of our interference rules. This finally comes down to the question whether it is better to confer the right of priority to the earlier date of application which can clearly and instantly be established, or to the date of conceiving the invention and reducing it to practice, which brings forth all the uncertainties, vagueness, which frequently make our interference proceedings so absurdly long, complicated and expensive. Our present interference rules are undeniably a real handicap to the inventor of limited means; and our system is detrimental to the best interests of the nation. Indeed, it delays the essential benefit of publication of the invention; furthermore, in some cases it becomes a positive danger to any industrial enterprise when nobody knows whether he is not infringing some unpublished patent rights which have been silently ripening to interference proceedings, protected by all the possible customary delays sanctioned by our rules of practice.

The German and British systems permit to file opposition proceedings within a certain period after a patent is allowed; this is an excellent simplified substitute for our interference proceedings. Members of the German patent office have invariably declared that they attach considerable importance to the maintenance of this system, because it tends to reduce the responsibility of the examiners and to enhance public confidence in the integrity and capability of the board of examiners; this in itself checks criticism to which such sensitive men as inventors are only too prone after they have encountered some disappointments in the office. I have noticed the same uniformly favorable opinion among German inventors, as well as patent attorneys and manufacturers, as to the advantages of the so-called opposition proceedings. Many of them, however, are of the belief that the British system, which allows opposition to a patent during a certain period *after* the latter has been printed and published is, however, more practical and expedient than the German method where opposition has to be filed *before* the patent has been printed, and before copies are readily obtainable except by means of special copies made from the pending application at the patent office.

As another check to worthless patents, the German law provides a safeguard in the method of annulment proceedings.

Such proceedings are quite distinct and independent from any infringement proceedings. Any person, whether sued for infringement or not, may apply to the patent office for the annulment of any patent if he can prove that, at the time of application the subject-matter was publicly known, or was claimed in a prior patent, or was illegally appropriated by the patentee. However, in the latter case, annulment proceedings can be instituted only by the person from whom the invention was appropriated.

In a similar manner, a person who believes he can prove that he is a prior inventor of an invention patented to another, and that the patentee has stolen his invention, can sue the patentee for an assignment of the patent to him.

There is still another safeguard in the German law, called the right of prior use (*Vorbenutzungsrecht*) which prevents the dangerous possibility which now exists in the United States, that a business enterprise, started in good faith, might be held up at any time on account of a long secretly pending patent application.

In Germany, any person who, at the date of application of a patent, has already used the invention in that country, or made the necessary preparations for such use, has the right to use the invention for the requirements of his own business in his own works; but this right can only be transferred to others together with the good-will of the business.

It should be noted here that sometimes the suggestion has been made to cut down entirely our examination system, as well as our interference system, and to come back to a plain registration system, which was abandoned in this country 76 years ago, but is now known as the French system. The report of the commission says emphatically:

"To return to such a system would be a backward step."

"While there are some persons interested in the subject who believe that the United States should return to the system of registering patents and allow all questions of validity and priority of invention to be determined in the courts, these persons are decidedly in the minority."

In France, a patent may exist for years before an examination is made as to priority and patentability, because such a scrutiny only takes place in case of a patent suit; and even then, the examination is not made by technical experts, but by the ordinary courts, who may or may not decide to hear experts. This absurd system accounts for the scant esteem with which patents are treated in the Latin countries where the French system is in use. The French system has certainly not shown the stimulating effect to invention and enterprise which the American system has introduced in such nations like Germany, England and the Scandinavian countries, which have adopted it in a more or less modified form.

It should be mentioned, furthermore, that in all countries where the French system is used, a patent really begins to be looked upon as serious after the corresponding German patent has been issued. This in itself, is the best tribute to the practical value of the preliminary examination system.

The most striking incongruity in our American system is that after a patent has been granted by a technical board, in infringement cases, this same patent is reexamined as to validity and patentability by a non-technical judge, in a non-technical court. This is the main reason why our system has been defined as "best in the world for lawyers and worst for inventors." (H. W. Leonard, *Electrical World*, Vol. 51, p. 1055.)

In this relation, the following words are very significant:

"The commission has been unable to see the benefit of the present system by which every question relating to a patent can be litigated in any part of the country.

"When the Patent Office shall have been furnished with adequate quarters and equipment and the most efficient personnel it will be time to consider to what extent the decision of this office ought to be final in patent matters. When that time comes, it may be found advisable to consider whether a patent should not be made valid by law to the extent of giving the patentee a right to an injunction in a case against alleged infringers.

"This would probably require the adoption of the practice of publishing applications when ready for allowance, with the opportunity for anyone to file opposition within a limited time, and if none were filed or it was decided that the patent should issue, it ought to be held valid for all purposes until declared invalid by court. Such a system would probably require also that any person claiming to be injured by the grant of a patent could file annulment proceedings within a limited period . . .

"There is a general complaint, although the commission is not advised as to the facts of the matter, that a grant of a patent is of no value to an inventor if it is in the interest of any person or corporation of financial strength to infringe it. The results after a patentee wins an infringement suit are often not of real benefit to him, for, if he survives the suit, the actual recovery of adequate damages is exceptional.

"It would seem that the remedy for many of the difficulties of the present situation regarding patents will be found in the development of the Patent Office as an administrative court in which all questions relating to patents, excepting the question of infringement, will be finally decided, subject only to a review by an appeal to a court of patent appeals, with possibly a provision for certain questions going to the Supreme Court. Giving such jurisdiction to the Patent Office, and to one court, will tend to the development of a system of patent law that will be a benefit to the public and a protection to real inventors."

The chapters 5 and 6 are devoted to the classification division and to the scientific library and the search room. They point out the existing defects and contain many excellent suggestions.

The fact that in the files of the patent office, there are still missing copies of 60,000 German patents and of 6000 French patents, is significant. It is true that for a certain period France discontinued publishing its patents.

Several other countries, for instance, Canada and Belgium, do not publish their patents excepting by title. Yet copies of every one of the patents published in those countries ought to be available in our search room; indeed, many of these patents contain important disclosures which have a direct bearing on the validity of the patents issued by the U. S. Patent Office.

It would not involve an exorbitant expense to have type-written copies made of the patents filed by those countries. A more satisfactory method would be to compel all countries which belong to the International Union to print every patent issued by them. This subject should be taken up at the next meeting of the International Convention, and could hardly cause any opposition, in as far as almost all countries belonging to the convention already print these patents.

A very detailed criticism of the totally inadequate conditions of the building and the equipment of the patent office is made, and specific recommendations are made for remedying this intolerable condition.

The commission overlooks the fact that the equipment of a new patent office will never be complete unless provision be made for a chemical, a physical and a mechanical laboratory, where simple direct tests can be made under the supervision of two or three experts—a chemist, a physicist, and an engineer; so that many simple questions which now baffle the examiners in their decisions on patentability could easily and quickly be decided by a direct test. Such a laboratory exists in the German Patent Office building.

The report is accompanied by several appendixes, all of which make interesting reading. These appendixes are as follows:

- A. History of the United States Patent System.
- B. United States laws and rules of practice relating to patents, trademarks and prints and labels.
- C. The German Patent law
- D. The English patent law.
- E. Discussion of the German patent law and patent procedure.
- F. A comparison of the patent laws and procedure in Germany, England and the United States.
- G. Methods of examining applications.

H. Publications of the patent office.

I. Statement of the business of the patent office.

J. Bibliography of the United States patent office.

K. Classification of patents and printed publications.

Specially instructive are appendixes E and F, written expressly by Prof. Dr. Albert Osterrieth and Mr. A. du Bois-Reymond, both of Berlin, and leading authorities on the subject. The latter paper not only compares the advantages of the laws of Germany, England and the United States, but points out their relative defects which experience has proved to exist and furthermore discusses the differences in procedure in these countries.

This discussion of the advantages and defects of the leading patent systems of the world, is a most valuable contribution and will be very useful in the consideration of changes that are suggested in the law and procedure of the patent system of the United States.

It is specially interesting to read the comments on the practical value of the so-called compulsory working clause or compulsory license clause in Germany and England, in view of the fact that an attempt is being made by the Oldfield Bill, and other proposed measures, to introduce this innovation in the United States.

In Germany, the compulsory working of patents has practically been abandoned and is merely kept up as a club to compel some countries like England, France and others into reciprocity treaties waiving the compulsory working of patents.

To the credit of the present commissioner of patents, it should be mentioned that he has already negotiated a treaty to that effect with Germany.

The United States, in accord with Germany, might have a decisive influence in abolishing this compulsory working clause in foreign countries, so irksome to American patentees, by passing a law whereby foreigners are compelled to work their patents in the United States, unless their country waives compulsory working of patents issued to American inventors.

The first Oldfield Bill had a clause of the kind, but it was so erroneously worded that in some paradoxical way, it gave superior advantages to foreigners over American inventors.

As to the compulsory working and compulsory license in Germany, we might best quote Prof. Osterrieth:

"In fact, very few patents have been revoked in Germany for non-working (one patent out of more than 2000). On the other hand, the working clause always threatens the patentee, hanging over his head like the sword of Damocles, as a great expert in patent matters once said. Besides, experience has shown that petitions for revocation are mostly entered by patent infringers, using the working clause as a defense.

"This explains why in the last 15 years, there has been a very strong movement in Germany for abolishing the working clause. This first induced the German Government to abolish the obligation of working by international treaties in the relations with Italy, Switzerland, and with the United States. And finally the old working clause of the first patent law was abolished by the law of June 6, 1911.

"Since this law came into force, i. e., July, 1911, no obligation of working a patent exists in Germany. No patent can be revoked on the ground that it is not being worked. Yet, considering the legislation of some countries which threaten foreign patentees with revocation of these patents, if the invention is exclusively or mainly manufactured abroad, the German Government resolved to provide for a similar clause, applicable at least against such countries where German manufacturers have to suffer from such legislation.

"It has therefore been stated in above-mentioned law of 1911, that a patent can be revoked, as far as international treaties do not provide to the contrary, if the invention is exclusively or mainly manufactured or carried out outside the German Empire, and its possessions. This clause does evidently not apply to citizens of the United States, even if an American has acquired a German patent from a patentee belonging to another country. Yet this might lead to abuses. Therefore, there has been provided a complimentary clause, saying that transferring

a patent to another person is ineffective if this transfer has been made only with the intention of avoiding revocation.

"According to the former German law a patent could be revoked, after expiration of three years from the date of granting, if it appeared in the public interest that permission to use the invention be granted to others, but the patentee refused to give such permission in return for adequate remuneration with adequate security. This clause has proved most ineffective as no single case of revocation of a patent on this ground has been known. Therefore, when the abolition of the working clause was discussed, it was suggested to do away also with that clause on the obligation of granting licenses. It was objected that cases might happen where the use of a patented invention by others than the patentee could be necessary for the public welfare, for instance, manufacturing certain drugs in case of an epidemic.

"This consideration seemed to justify the insertion of the following clause in that new law of 1911:

"If the patentee refuses to grant license to another for using the invention upon the offer of an adequate compensation and security, such grant for using the invention can be allowed (compulsory license), if such granting seems necessary in the public interest. The grant may be limited or subject to special conditions."

This detailed report of the Commission on Economy and Efficiency is supplemented by some specific recommendations as follows:

1. That a new building specially designed, equipped, and furnished be constructed on a suitable site in the city of Washington, for the exclusive use of the United States Patent Office.
2. That the number of officers and employees of the United States Patent Office be increased, and the increases and readjustments of salaries be made as shown in detail in this report involving an increase of 36 in the number of employees and a total increase of \$236,550 in the pay roll.
3. That the Commissioner of Patents be the head of the Patent Office; that his duties be the same as are now prescribed by law, excepting that he be relieved from the consideration of cases on appeal; that he be aided by an assistant commissioner and seven supervising examiners in the administrative work, including control of the methods and procedure of the 43 examining divisions in the allowance and rejection of applications for patents.
4. That one appeal within the United States Patent Office be eliminated; that the number of members of the board of examiners in chief of the Patent Office be increased from three to five; that all appeals within the office be taken to that board; that its decision be the decision of the Patent Office; that the appeal therefrom be to the Court of Appeals of the District of Columbia, as now allowed from the decisions of the Commissioner of Patents.
5. That the fee for filing an application be increased from \$15 to \$20; that appeal fees be adjusted to the conditions arising from the elimination of one appeal; that a fee of 25 cents be charged for each additional patent, etc., included in one instrument presented for record; that all fees be paid directly to the Patent Office; that refundment of fees paid by mistake be made by the financial clerk and not by warrant from the Treasury.
6. That the life of a patent be so limited as to expire 10 years from the date of filing the application therefor, excluding the time (not exceeding two years) during which an application may be involved in interference.
7. That the work of reclassifying patents and digesting of printed publications, and providing facilities for simplifying and making more accurate the search, be recognized by an appropriation for an adequate force to be employed upon such work.
8. That the subscription price of the Official Gazette be increased from \$5.00 to \$10.00 and the method of distribution to libraries be changed to reduce the number of copies so distributed.
9. That all the work of producing the publications of the

Patent Office, including copies of patents, be done at the Government Printing Office.

10. That an appropriation be made for the repair of the rooms occupied by the Patent Office and for the installation of suitable lighting and ventilating facilities and for the purpose of new furniture and equipment.

Yonkers, N. Y.

Essentials in the Making of the Finer Steel Sheets

By John G. Homan

Wood is combustible, fragile, increasing in price, decreasing in quality and availability; accordingly other materials are naturally sought for substitutes. Where automobile bodies, certain furniture, interior trimmings of houses, etc., are concerned, sheet steel, with clean, highly finished surfaces has found welcome. The relation this class of sheets bears to the common and familiar "One Pass" material is about the same that hemlock or elm might bear with rosewood or lignum vitae.

For instance, where the architect calls for the splendid walnut-finished doors, etc., for the modern fireproof hotel, he will be satisfied with no less than a product which requires careful inspection to determine the body material. His art calls for finish and imitation, while his engineering demands durability and fireproofing qualities.

The sheet steels for this work have much in common with the woods they supplant; they are necessarily of fine texture or grain, and the practice which produces the commoner material can no more produce satisfactory auto sheets or metal furniture steel than a cupola could make armor plate.

It is the intention of this article to relate something of the essentials in the manufacture of these highly finished steels, as is carried on by a concern devoting all its energies and fabricating equipment to these products.

The steel making is carried on in a plant equipped with basic open-hearth furnaces of moderate capacity; moderate capacity because of the satisfaction obtained in the cleaning action of such furnaces, due likely to the larger value of the ratio of slag surface to bath volume and other considerations not available in the larger furnace of 60 or 100 tons capacity. The fuel is natural gas and has therefore the advantage of easy regulation, sharp thermal value, and absence of sulphur. The raw materials are as usual, pig iron and scrap, both of which are selected and secured from sources which insure certain regularity of composition.

The policy in steel making of producing clean steel from clean materials, rather than making questionable material and answering the question in the ladle, with all sorts of deoxidizers, etc., is followed, as it is essential that the steel be clean; and the cleanliness is to be determined not by the testing machine, but by the material accepted or rejected by the finisher.

The casting is done by the bottom cast method and has many advantages already familiar to those who read this article; the disadvantage is expense. Here, as in all the processes, care is needed, the runner brick and pouring system must be clean. Compressed air is useful in removing particles of brick, etc., which would otherwise contaminate good steel.

When cast and cool the ingots are stripped from their molds and sprues connecting them broken, separating the ingots, which are then piled in stock. From this stock they are taken to the heating furnaces preparatory to reduction. During the heating a rather heavy covering of scale is formed.

The first mechanical reduction is accomplished by the blows of an 8-ton steam hammer. The action of the hammer on this steel is very much the same as for the fine hammered tool steels, it accomplishes a homogenous refining of the grain; a refinement which no rolling method in the writer's experience has been able to show. At the first blow of the hammer almost

all of the scale envelope falls away from the ingot, carrying with it any surface impurities from unclean molds. The final blow finishes the 1500-lb. ingot into billets of section about one-fourth that of the ingot. From the hammer these billets are conveyed on buggies by men to the bar mills. The billets are not reheated after leaving the hammer.

At the bar mills the billet is roughed down in five passes to a suitable size for the finishing stand of rolls, in which it is finished in five more passes to a bar 8 in. wide and of weight corresponding to the sheets to be made from it. At all times when possible water is used on the hot bars; one of its important effects being the tendency of the steam formed to remove surface scale, if any. The long, finished hot bars are conveyed one at a time to a bar shear where sheet bars are cut to length under the inspection of a man who throws aside any bad looking material. The selected bars are allowed to fall into a vat of circulating cold water, where they are further cleaned by the explosive action of the steam formed on their surfaces.

For certain classes of highly finished product the bars thus made are cleaned by pickling in a solution of sulphuric acid, but in the manufacture I am outlining the steel is made clean and every effort is used to keep it clean, so that ordinarily little is gained by the bar pickling.

The bars are rolled into sheets by very heavy mills; the main advantage being the ability of such rolls to produce sheets from bars relatively cooler than the usual practice would permit. The rolls in question are 38 in. in diameter and 44 in. long and weigh approximately 12,000 lb. each. The stands are correspondingly heavy and designed to allow as little elasticity as possible. Brushes and water are used freely at these mills.

The large roll has the advantage of the larger periphery and the consequent longer life of a turning, and as they are turned up much more frequently than the ordinary sheet mill rolls, they will produce material with much more uniform gauge because of this fact.

While in ordinary practice the roughing or "soft" mills are little regarded as to condition, in this procedure utmost care is bestowed on them. Attempt is made to produce a sheet so uniform in physical and mechanical make-up at the hot mills that the subsequent treatment will have a uniform action because of a uniform base.

The furnace in which the bars are heated, as well as that in which the sheet packs are heated, requires care that appeals to the tonnage producer in the ordinary mill as impractical. Here care is required that can be exercised by a skill that comes only from experience. The design of the furnace, the kind of fuel and the quality of flame are very important considerations.

The finished packs are slowly cooled and no water is used on them as is sometimes required to assist the opening process. When cool the packs are sheared and the sheets separated or "opened." The temperature of rolling, together with the chemical composition of the sheets allow easy "opening."

After shearing, various methods or procedures may be followed, depending upon the requirements of the user. It is in order to say that these requirements are very different even with manufacturers using the materials for the same purposes, so that a finished sheet which appeals to the idiosyncrasies of one purchaser may be too hard, too soft, or lack certain surface characteristics that may be desired by his fellow craftsman.

After shearing, cold rolling is usually in order, if so, the material is conveyed to the cold rolls. In the works where fine goods are made two classes of cold mills are required, one for the beginning or rough work and the other for the finishing passes. Both kinds require great care because the little waves and small marks that are always present in the very best grades of common sheets are absolutely out of question here. When a sheet is fed into the cold rolls the sharp edge of the end of it marks the rolls so that after a little while the rolls become almost covered with parallel lines from this cause, so that the following sheets have these marks transferred to their surfaces and are objectionable. The marks must be removed.

and it is the function of the finishing cold mills, and intermediate processes, to remove them as well as many other errors that emphasize themselves only when one has to deal with the rigid requirements of the usual buyers of highly finished sheets.

After cold rolling one or more passes through the cold mills, the sheets may be cleaned by pickling in acid, washing and drying. This is essentially a hand work and requires all the patience and skill of a good launderer because some sheets respond quicker than others and some require attention that machines of any type familiar to the writer cannot give.

After this important operation, for a certain finish, more cold rolling may be in order, or for another requirement annealing may be required. This latter operation is carried out by placing the sheets in a pile on a cast steel plate, or "bottom," and covering the pile with an air-tight wrought-steel box. This combination is sealed at the junction of the box and bottom with sand and run into a furnace where heat is applied to the extent required. This operation is usually in the hands of an experienced foreman who knows how to apply the heat properly, which means not only time, temperature and uniformity, but the expert knowledge of the phenomenon that what appears from outward signs to be going on inside of the annealing box may or may not be going on. The annealer must know when and how to draw the boxes and he must, of course, be familiar with the causes that produce even the little effects usually overlooked entirely by the ordinary sheet annealer. Lately we have assisted the skill of this workman with that very useful tool of the metallurgist, the pyrometer. Equipment is here, as usual in this manufacture, of utmost importance; fuel, furnace design, type of boxes, etc., require detailed study.

The operations mentioned above in brief detail constitute the more important ones, and for the different kinds of goods they are applied in different combinations of routine. The thing least altered is chemical composition of the steel, probably because the one used is known to give the better surface tendencies and likely also because, for the use intended, sufficient hardness or softness can be had by skillful working.

Besides the above-mentioned processes there is an adjunct one connected with that of annealing and which is known as "deoxidizing." While the theory of this process is apparently simple, the real work is more or less difficult. The process is a matter of breaking up by heat the oxide film which covers the usual sheet of steel and preventing its reformation while cooling by filling the box in which the heating is done with a reducing or neutral atmosphere, usually natural gas. The process should leave a very clean, silvery surface, and it is sometimes spoken of as "white annealing."

Then there are operations for final levelling of the sheets, of these the "patent" or "stretcher" leveller is most effective, though very wasteful. The patent leveller is a machine which grips the ends of a pack of three or four sheets in vice-like jaws and stretches them flat by means of a hydraulic system. This operation hardens the material somewhat. Where the jaws of the machine grip the sheets indentations are obviously made which require another shearing operation as well as the loss of the marred ends of the sheets.

The roller leveller is a small machine consisting of two series of parallel rolls about 5 in. in diameter. The rolls are so placed that when a sheet is passed through the machine one series of rolls is above the sheet and one series below. The purpose of this process is to remove buckles, hellies, etc., from sheets with minimum hardening effect.

The composition of steel which seems to offer the best all around usefulness when subjected to the processes above mentioned seems to be one of the more pure iron content, i. e., carbon about 0.12 per cent and manganese about 0.40 per cent, with sulphur in the neighborhood or perhaps below 0.025 per cent.

For auto sheets of the highest class considerable cold rolling is necessary, the first two or three passes reduce the thickness somewhat and seems to definitely refine the grain. The hardness produced can be removed by annealing, which process is up to the skill of the annealer, as the degree of hardness in this material is subject to the peculiar wants of the user.

To prevent corrosion in transit, etc., these finished materials are often oiled with an acid-free heavy oil.

Follansbee Brothers Company.
Pittsburgh, Pa.

Laboratory Apparatus for the Exact Analysis of Flue Gas

In many manufacturing plants apparatus are now used and are proving very successful for determining a few of the constituents of flue gas. In some automatic CO_2 recorders are employed, in others samples are collected at intervals or during extended periods of time and analyzed by means of various types of gas-analytic apparatus, such as those devised by Orsat, Hempel, Elliot, and Bunte. With any of these apparatus results can be obtained by which the performance of a boiler furnace can be intelligently supervised and the introduction of these apparatus has resulted in important advance in efficiency of operation.

If for technical research the exact composition of the waste gas is desired, however, the analysis is more complicated and has been the subject of an investigation at the Bureau of Mines.

The results of this investigation are described in a paper by **George A. Burrell and Frank M. Seibert** (Technical Paper 31 Bureau of Mines). From this paper the following extracts are taken:

For the determination of carbon dioxide, oxygen, carbon monoxide, hydrogen and methane in flue gas during combustion tests conducted by the Bureau of Mines the authors have used the apparatus shown in Fig. 1.

This apparatus is a modification of the well-known Haldane apparatus. (J. S. Haldane and C. L. Foster, *The Investigation of Mine Air*, 1905, p. 100.) It has been simplified from the original pattern in that the pipettes are all placed in a common train. Three 3-way stopcocks have been replaced by three 2-way stopcocks, and a simpler pipette has been

FIG. 1.—LABORATORY FORM OF APPARATUS FOR THE EXACT ANALYSIS OF FLUE GAS

provided for the alkaline pyrogallate solution. The essential features and the method of working remain the same as proposed by Dr. Haldane for analyzing mine air.

The burette *d* contains mercury, and has a total capacity of 21 c.c. The bulb of the burette, which is not graduated, has a capacity of 15 c.c. The stem of the burette has a capacity of 6 c.c. and is graduated at 0.01 c.c.

The three pipettes shown are the potassium-hydroxide, *a*; the slow-combustion, *b* and the alkaline pyrogallate, *c*. The reservoir of the alkaline pyrogallate pipette is placed back of the stand and is provided with a rubber bag to prevent access of air to the alkaline pyrogallate solution.

The surfaces of the liquids in the reservoir bulbs must, in all cases, be at the same level as the surfaces of the liquids in the corresponding pipettes when the liquids are brought to the marks represented at *e*, *f*, and *g*, in the figure. This condition is necessary to prevent a difference in pressure acting against the columns of the liquids in the pipettes when the gas sample is transferred from the burette to the different pipettes.

To perform an analysis, the liquids in the three pipettes are brought exactly to the marks, *e*, *f*, *g*, on the capillary tubes. If an analysis has been recently made, this preliminary step is unnecessary, but if the apparatus has stood unused for some time, the solutions usually have to be adjusted before making an analysis. The three-way stopcock *h* is turned to communicate between the outside air and the compensating tube *i*, so that the pressure in the tube may equal that of the atmosphere, and

is then turned to communicate between the tube *i* and the column of liquid in the capillary tube *o*. The gas sample is transferred to the burette by displacing it with mercury.

The first 5 or 10 c.c. of gas drawn into the burette *d* from the sample container is not retained, but is used to sweep the air out of the connections between the burette and the sample container. For this purpose an extra 3-way stopcock is placed between the burette and the sample container. Gas is then drawn into the burette until the mercury is depressed somewhat below the 21 c.c. mark; then, with the burette stopcock *k* closed, the gas is placed under pressure by slightly raising the level bulb *p*. Next the burette stopcock *k* is opened to the air for a second to bring the gas in the burette to atmospheric pressure. Before reading the volume of gas inclosed, the stopcocks at *k* and *m* are turned so that communication is made between the burette and the potassium-hydroxide solution pipette *a*.

If the directions for manipulating the apparatus have been followed with care there is only a slight movement of the potassium-hydroxide solution at *e*. If, through failure to follow directions exactly, there is a decided movement of the solution, error will ensue. A resulting increase of pressure causes an absorption of some carbon dioxide before the reading is taken, and a decrease of pressure pulls the potassium-hydroxide solution into the horizontal capillary tubing, thereby ruining the value of the combustion data subsequently obtained.

By slightly raising or lowering the level bulb *n* the surface of the potassium-hydroxide solution is brought exactly to the mark *o* in the capillary tube.

The potassium-hydroxide solution is brought to the mark *e* above the pipette by a slight movement of the mercury in the burette, and the volume of gas is read to the third decimal place. The burette can be read to 0.002 c.c. The gas is then passed into the potassium-hydroxide pipette, and the carbon dioxide is entirely removed by passing the gas back and forth between the burette and the potassium-hydroxide pipette about four times. In no case should the mercury in the burette be raised above the stopcock *k*. The reduction in volume of the sample caused by the removal of the carbon dioxide is recorded.

The sample is next passed into the slow-combustion pipette *b*. The platinum coil in this pipette is No. 30 (B. & S.) wire and is in contact with platinum wires in two glass tubes filled with mercury. Each wire is sealed through the bottom of its tube and to the projecting ends are attached the copper wires for carrying the electric current. The platinum coil is brought to a white heat by a current of about 5 amp. About two minutes is required for the complete oxidation of the combustible gases contained in the sample. The gas remaining in the capillary tubing is brought in contact with the platinum spiral by passing the sample back and forth between the burette and the combustion pipette several times, care being taken that the mercury in the combustion pipette is not raised to the platinum spiral in the pipette. Finally, the current is broken and the pipette allowed to cool. Cooling is hastened by playing a stream of compressed air upon the pipette. When cool, the gas is transferred to the burette and the contraction in volume is recorded.

The residual gas is then passed into the potassium-hydroxide pipette *a* to absorb the carbon dioxide produced by the combustion. After the contraction in volume caused by this absorption has been measured, the gas is passed into the pipette *c* containing the alkaline pyrogallate solution to absorb oxygen.

At this stage of the analysis the capillary tubes are manifestly filled with residual gas that contains oxygen. In order to avoid sweeping them out by dilution and to obtain the last trace of oxygen, the mercury in the combustion pipette is brought to the stopcock *r* by raising the bulb *j* and the potassium-hydroxide solution is brought to the stopcock *m* by raising the bulb *n*. The oxygen is completely absorbed by passing the gas back and forth between the burette and the alkaline pyrogallate solution five or six times.

The alkaline pyrogallate solution is finally brought exactly to the mark *g*; the mercury and the potassium-hydroxide solution are brought to their respective marks at *f* and *e*, and the reduction in volume of the gas is measured. The oxygen percentage thus determined represents the oxygen remaining after a certain volume has been consumed in the burning of the combustible constituents. To determine the volume of oxygen consumed, a separate determination is made by drawing a fresh portion of the sample of gas into the burette and passing it in turn into the potassium-hydroxide and alkaline pyrogallate solutions and measuring the reduction in volume produced. The total oxygen content thus determined, minus the residual oxygen already found, represents the oxygen consumed.

Other burette readings are made in a manner similar to that in which the original volume of the sample was read. After combustion, for instance, the gas is withdrawn to the burette and the mercury in the combustion pipette brought exactly to the scratch at *f*. The stopcock at *r* is closed and the one at *m* opened. The solution in the capillary tube is brought to the scratch *o* by raising or lowering the level bulb *n* and the solution in the potassium-hydroxide pipette *a* is brought to the mark *e* by a slight movement of the mercury in the burette. The burette is then read.

From the contraction, the carbon dioxide produced by the combustion, and the oxygen consumed, the methane, carbon monoxide, and hydrogen may be calculated by the following well-known equations:

An analysis such as is described above can be performed in 35 minutes.

Minor Details.—Heavy-wall pure-gum tubing is used on all connections, and the stopcocks are kept well lubricated. The stopcock grease used is made by adding one part paraffin and three parts vaseline to one part pure gum rubber. The rubber is melted, the other ingredients are added, and the mixture is then heated to melting for several minutes. The inner walls of the burette and the compensating tube are kept slightly moistened with water. The instrument should be protected from drafts and the water in the water jacket, each time before burette readings are made, is agitated by blowing air through it, thus insuring uniformity of temperature throughout the water jacket.

It is desirable, if compressed air can be obtained, to keep air bubbling through the water jacket during the entire analysis.

TABULATED RESULTS OF DUPLICATE ANALYSES OF A SAMPLE OF FLUE GAS

Observation or Calculation	FIRST ANALYSIS				SECOND ANALYSIS			
	Volume 1	c.c. 2	Volume 3	c.c. 4	Volume 5	c.c. 6	Volume 7	c.c. 8
Volume of sample taken	20.178		20.300		20.379		20.300	
Carbon dioxide (after caustic polish)	18.181	0.90	18.291	0.90	18.361	0.91	18.288	0.91
Oxygen (after pyrogallate solution)			16.373	9.45			16.373	9.43
Total volume of residual gas	18.181				18.361			
Volume after burning	18.006				18.181			
Contraction	0.175				0.175			
Volume after carbon-dioxide absorption	17.800				17.982			
Carbon dioxide produced	0.206				0.204			
Volume after oxygen absorption	16.022				17.101			
Residual oxygen	1.778				1.791			
Oxygen consumed	0.128				0.127			
Methane	0.01				0.02			
Carbon monoxide	1.02				0.98			
Hydrogen	0.24				0.23			

Bubbles of water mercury must be kept out of the horizontal capillary tubing. It is scarcely necessary to add that a trace of potassium-hydroxide solution left in the tubing will ruin the

value of the combustion analysis. The tubing from *o* over to the compensating tube *i* must also be kept clear of detached bubbles of the potassium-hydroxide solution.

Recording of Results.—The following results of two duplicate analyses show the details observed and the calculations made. As will be observed, the analyses are of flue gas from a boiler furnace operating under very poor conditions:

In column 1 are shown data representing the changes in volume of the gas sample at different stages of the analysis.

In column 2 are shown the proportions of carbon dioxide, carbon, monoxide, hydrogen, and methane calculated to a percentage basis.

In column 3 are shown the observed data involved in the separate oxygen determination.

The final figures representing the percentages of carbon dioxide and of oxygen are shown in column 4.

In columns 5, 6, 7, and 8 are shown the readings and results of the duplicate analysis.

From the combustion data calculations were made to show the errors that might result if the oxygen consumed were not determined, and the results were calculated to carbon monoxide and methane. The possible errors are indicated below:

POSSIBLE ERRORS FROM FAILURE TO DETERMINE OXYGEN CONSUMED

	First Analysis, Per Cent	Second Analysis Per Cent
Carbon monoxide	0.78	0.76
Methane	0.24	0.24

A New House Organ

We have received No. 1 of Vol. 1 of *The Abrasive Age*, "devoted to the better use of abrasives," and published monthly by the Carborundum Company, of Niagara Falls, N. Y. It is interestingly written, well printed, and nicely illustrated. There are articles by F. B. Jacobs on disc grinding, by A. B. Maine on garnet paper and cloth in the chair factory, by Edward Edwards on glass grinding, and numerous smaller notes. We wish this new journal a happy and useful career in furthering the already great popularity of artificial electric-furnace abrasives.

The selection of proper screens in any industry where products are sized is one of the most important branches of that industry. This subject has received close attention at the hands of W. S. Tyler Company, Cleveland, Ohio, and is well treated in that company's artistic catalog No. 40. The company is scientifically equipped to render screen users all possible assistance in solving their screen problems. A testing laboratory contains 2000 variations of screen sections, different in size of opening, mesh, metal, and diameter of wire. From the catalog it should be possible to select a screen suitable for almost any purpose, as over 200 styles are illustrated and fully described. The catalog contains also some valuable information and data on screen analysis, with methods of plotting such an analysis in two different forms. Special attention is given to standard testing sieves, with openings increasing in the ratio of the square root of 2, or 1.414. For closer sizing another series has openings increasing in the ratio of the fourth root of 2, or 1.189.

The production of copper in Russia has increased greatly in the last few years, according to a report from the Consul-General at Moscow. Seven years ago the output was about 10,000 tons, and did not meet half the requirements of the country. In 1907 the production was 14,750 tons; in 1910, 23,000 tons; in 1911, 26,500 tons, and the estimated output for 1912, 30,000 tons. The production of electrolytic copper in Russia started in 1907, and in 1911 another plant was started. At present all domestic requirements of electrolytic copper are met with metal of Russian origin.

The Determination of Sulphur in Ferro-Vanadium

By Wm. W. Clark

Sulphur cannot be determined in ferro-vanadium by the evolution method, as varying amounts of the sulphur remain in the evolution flask as insoluble sulphides. Every possible method of evolution has been tried and it has been found, that in each case, some of the sulphur remains in the flask. The modification which gave the best results was the addition of 1 gram metallic aluminum and to cc. hydrofluoric acid to the alloy in the flask, using dilute hydrochloric acid as the dissolving agent. About 80 per cent of the total sulphur was the maximum that could be evolved, while on some grades of alloy the results would run as low as 10 per cent of the total sulphur. C. M. Johnston mentions this fact in his book on the Chemical Analysis of Special Steels, Steelmaking Alloys and Graphites, page 16.

The barium chromate method, which is used to determine sulphur in coal and coke, was tried, but it requires, first, the removal of the vanadium, and finally the iron. The method necessitates several filtrations and unless the conditions are kept absolutely constant, the results vary beyond checking limits.

The old gravimetric method is the only one by which the sulphur can be accurately determined in ferro-vanadium. The details of the method in use are as follows:

A factor weight (1.373 grams) of the finely powdered alloy is dissolved in a mixture of 40 cc. concentrated hydrochloric and 10 cc. concentrated nitric acid, and 1 gram sulphur free sodium chloride. The solution is evaporated to dryness, moistened with strong hydrochloric acid and again desiccated. If a red granular precipitate settles out during evaporation, causing the solution to spit, more hydrochloric acid must be added. If the alloy is refractory to these acids, it is fused in a nickel crucible with a mixture of 3 grams magnesium oxide and 7 grams sodium peroxide. The magnesium oxide is used to deaden the reaction, as powdered ferro-vanadium, when heated with sodium peroxide, combines so rapidly with the oxygen from the peroxide, that it melts the crucible and is almost an explosion. The fused mass is dissolved in the least possible amount of water, acidified with strong hydrochloric acid, adding about 40 cc. excess, and evaporated to dryness.

The residue in each method is dissolved in 60 cc. strong hydrochloric acid, diluted to 400 cc. with boiling water, and the silica removed by filtration, washing the precipitate free from salts with hot 3 per cent hydrochloric acid. The filtrate is heated to boiling, 10 cc. of a saturated solution of barium chloride added, the solution boiled for 10 minutes, and set aside over night in a warm place. It is then filtered on a OO Munktell filter, washed free from salts with a hot 1 per cent hydrochloric acid, 1 per cent barium chloride solution, and finally with a hot 3 per cent hydrochloric acid solution until free from all soluble barium salts. When washing the barium sulphate precipitate from the soda fusion, it must be remembered that soda is hard to remove from barium sulphate, and the washing must be continued with the barium chloride solution considerably longer than when washing the precipitate from the acid solution of the alloy.

The precipitate and paper are ignited in a weighed platinum crucible cooled and weighed. The difference in weight, multiplied by 10, gives the percentage of sulphur in the alloy.

The above method, while slow, does not require much of the operator's time, not taking more than 3 hours of actual work on 6 determinations. It is very accurate, and results should check within 0.005 per cent sulphur.

American Vanadium Co., Bridgeville, Pa.

Congress has authorized the expenditure of \$2,596,000 for a building to accommodate the Geological Survey, the Bureau of Mines, the Reclamation Service and the Indian Office, all bureaus of the Interior Department. Plans for construction will go forward at once.

The Heat Balance of the Open Hearth

An Account of an Elaborate Heat-Efficiency Test Made on Two 60-ton Open Hearth Furnaces. By Sidney Cornell.

There is a deplorable lack of any printed data in English in relation to the open-hearth furnace from a metallurgical standpoint. Hence, the following is published with the hope that the data given may be criticized, and lead to further information on this most important subject.

The modern blast furnace, as operated today, is run with due consideration for known chemical and metallurgical laws, but this is not so much the case with the open-hearth furnace. The advantage of a change in this direction can be appreciated, and the time has come for betterment of the conditions as existing in open-hearth practice from a metallurgical standpoint.

The data from which this test was figured was obtained at the Duquesne Works of the Carnegie Steel Company. The open-hearth furnaces tested were two 60-ton furnaces, together with their four Hughes mechanically operated gas producers. It was necessary to test two furnaces due to the fact that the gas flues from the four producers are not separated, hence the gases from four producers feed two open-hearth furnaces. The hearths of the furnaces tested were 32 ft. 0 in. x 14 ft. 9 in., and the Hughes producers were of the standard design for that type, and capable of gasifying 25 lb. of coal per square foot of grate area per hour.

The test covered an entire week, starting when the steam was turned on the producers, the Saturday of one week, and terminating when the steam was turned off the producers the Saturday of the following week, thus covering a period of 161 hours and 32 minutes, and during which time twelve heats were made in one furnace and 11 heats were made in the other, with a total tonnage for the two furnaces of 1,615 tons for the week.

The conditions under which the data for this test was obtained, were strictly operating conditions, and the heat balance is figured from the average of all collected data.

The log of the test follows:

FURNACE CHARGES

Furnaces	No. 89 Pounds	No. 90 Pounds	Total Pounds
Charges:			
Hot metal	938,800	871,200	1,810,000
Cold pig	117,000	38,400	155,400
Blooms	474,500	479,200	953,700
Plate		31,500	31,500
Ingot huts	55,000	40,600	95,600
Rail scrap	25,500	38,000	63,500
Tin scrap	43,000		43,000
Turnings	5,500		5,500
Steel scrap	86,900	81,000	167,900
Stirring rods	2,400	2,200	4,600
Additions:			
Hot metal	122,300	143,900	266,200
Ferro manganese	8,600	5,300	13,900
Ferro silicon	650	400	1,050
Roll sulphur	245	120	365
Ore charged	185,500	139,100	324,600
Ore added	61,000	30,000	100,000
Cinder charged	5,000	4,100	9,100
Scale charged	8,900		8,900
Limestone	126,100	122,400	248,500
Fluor spar	2,250	2,200	4,450
Dolomite	57,000	53,000	110,000
Coal (anthracite slack)	1,300	2,150	3,450
Pounds product	1,905,450	1,715,040	3,618,490
Injoints made	309	271	580
Heats made	12	11	23
Average analysis:			
C	0.320	0.462	0.388
Mn	0.506	0.484	0.495
S	0.0426	0.0430	0.0428
P	0.0174	0.0188	0.0238
Si		0.034	0.0200

The starting point in figuring the distribution of heat in an open-hearth furnace is naturally the fuel, hence the following log was necessary in order to get the time of operation of the Gas Producers. The logs of the operation of furnaces 89 and 90, as here given, put the gas producer operation on a test basis, and which summated gives the steam blown in the operation. Summating the data in relation to the amount of gas used during the operation of the furnaces, and taking into consideration the time the producers were off for cleaning, we get the table showing the steam blown.

OPEN-HEARTH FURNACE NO 89

Date	Hr.	Min.	Remarks
Saturday			
20th	11:25 A.M.		Commenced charging for a soaker.
20th	7:26 P.M.		Gas producers started. Steam on.
20th	8:00 P.M.		Ended charging scrap for soaker. Gas on.
21st	6:45 A.M.		Hot metal added. Gas lowered.
21st	2:30 P.M.		Commenced tapping heat, No. 89,476. No. 1
21st	2:43 P.M.		Finished tapping heat, No. 89,476. Start patch.
21st	2:50 P.M.		Finished patching bottom. Gas off.
21st	3:02 P.M.		Gas on again.
21st	3:15 P.M.		Commenced charging for heat, No. 89,477.
21st	6:15 P.M.		Finished charging.
22d	4:57 A.M.		Commenced tapping. Heat No. 89,477. No. 2
22d	5:40 A.M.		Finished tapping. Gas lowered.
22d	5:25 A.M.		Gas taken off furnace
22d	5:51 A.M.		Gas put on again
22d	8:07 A.M.		Commenced charging for heat No. 89,478. No. 3
22d	8:40 A.M.		Finished first charge.
22d	11:25 A.M.		Hot met-1 to furnace. Gas lowered.
22d	11:40 A.M.		Gas increased.
22d	5:50 P.M.		Tapping commenced on heat No. 89,478. No. 3.
22d	7:05 P.M.		Tapping finished, making bottom. Gas off.
22d	7:30 P.M.		Bottom made. Gas put on again.
22d	7:30 P.M.		Commenced charging for heat No. 89,479. No. 4
22d	8:30 P.M.		Finished charging.
23d	6:15 A.M.		Hot metal added. Gas lowered.
23d	4:49 A.M.		Commenced tapping heat No. 89,479. No. 4
23d	5:15 A.M.		Gas taken off, tapping finished. Make bottom.
23d	6:00 A.M.		Gas put on again. Bottom made.
23d	6:25 A.M.		Commenced charging for heat No. 89,480. No. 5
23d	9:12 A.M.		Hot metal added. Gas lowered.
23d	9:30 A.M.		Finished charging. Gas increased
23d	4:22 P.M.		Commenced tapping heat No. 89,480. No. 5
23d	4:32 P.M.		Finished tapping. Gas taken off
23d	5:20 P.M.		Gas put on again. Bottom made.
23d	5:40 P.M.		Commenced charging for heat No. 89,481. No. 6
23d	8:10 P.M.		Finished charging.
24th	3:32 A.M.		Commenced tapping heat No. 89,481. No. 6
24th	3:40 A.M.		Tapping finished. Bottom making. Gas off
24th	4:06 A.M.		Gas on again. Bottom made.
24th	4:15 A.M.		Commenced charging for heat No. 89,482. No. 7
24th	6:10 A.M.		Hot metal added. Gas lowered
24th	6:15 A.M.		Charging completed. Gas increased
24th	4:15 P.M.		Commenced tapping heat No. 89,482. No. 7
24th	4:25 P.M.		Tapping complete. Bottom making. Gas off
24th	5:10 P.M.		Bottom made. Gas put on again.
24th	5:20 P.M.		Commenced charging for heat No. 89,483. No. 8
24th	9:05 P.M.		Charging finished
25th	4:40 A.M.		Commenced tapping heat No. 89,483. No. 8
25th	4:50 A.M.		Tapping complete. Making bottom. Gas off
25th	5:30 A.M.		Bottom made. Gas put on again.
25th	8:35 A.M.		Commenced charging for heat No. 89,484. No. 9
25th	11:00 A.M.		Hot metal added. Gas lowered
25th	11:15 A.M.		Gas increased. Hot metal in. Charge all in
25th	4:55 P.M.		Tapping commenced on heat No. 89,484. No. 9
25th	5:10 P.M.		Tapping completed. Gas lowered
25th	5:45 P.M.		Bottom made. Gas put on again
25th	6:55 P.M.		Commenced charging for heat No. 89,485. No. 10
26th	3:41 A.M.		Finished charging
26th	3:53 A.M.		Commenced tapping heat No. 89,485. No. 10
26th	3:53 A.M.		Tapping finished. Gas off. Bottom making
26th	4:40 A.M.		Gas on again. Bottom made
26th	6:15 A.M.		Commenced charging for heat No. 89,486. No. 11
26th	8:38 A.M.		Hot metal added. Gas lowered
26th	8:50 A.M.		Charging completed. Gas increased
26th	4:40 P.M.		Commenced tapping heat No. 89,486. No. 11
26th	4:50 P.M.		Tapping completed. Gas off. Making bottom
26th	5:13 P.M.		Bottom made. Gas on again
26th	6:07 P.M.		Commenced charging for heat No. 89,487. No. 12
26th	8:20 P.M.		Charging completed.
27th	3:35 A.M.		Hot metal added. Gas lowered and increased
27th	4:15 A.M.		Commenced tapping heat No. 89,487. No. 12
27th	4:58 A.M.		Tapping completed. Gas off. Making bottom
27th	6:00 A.M.		Bottom made. Gas on again low increased
27th	9:35 A.M.		Cold pig charged for soaker
27th	12:58 P.M.		End of test. Steam off producers

OPEN-HEARTH FURNACE. No. 90

Date	Hr.	Min.	Remarks
Saturday			
20th	7:26 P.M.		Gas producers started. Steam on.
20th	8:30 P.M.		Furnace still empty. Gas on, low.
21st	1:45 A.M.		More gas used.
21st	3:15 A.M.		Gas again increased.
21st	8:55 A.M.		Gas taken off.
21st	8:55 A.M.		Gas put on again.
21st	10:43 A.M.		Charging cold pig. Charging commenced.
21st	11:25 A.M.		Gas put on full.
21st	3:25 P.M.		Charging complete for heat No. 90,500. No. 1.
21st	10:25 P.M.		Commenced tapping heat No. 90,500. No. 1.
21st	10:40 P.M.		Finished tapping. Making bottom. Gas off.
21st	11:20 P.M.		Bottom made. Gas on again.
22d	12:32 A.M.		Commenced charging for heat No. 90,501. No. 2.
22d	12:57 A.M.		Gas increased.
22d	3:15 A.M.		Hot metal added. Gas lowered.
22d	3:30 A.M.		Charging completed. Gas increased.
22d	9:30 A.M.		Hot metal added. Gas lowered.
22d	9:41 A.M.		Commenced tapping heat No. 90,501. No. 2.
22d	9:54 A.M.		Tapping complete. Making bottom. Gas off.
22d	10:12 A.M.		Making bottom complete. Gas on again.
22d	11:25 A.M.		Commenced charging for heat No. 90,502. No. 3.
22d	2:24 P.M.		Gas increased more.
22d	3:45 P.M.		Hot metal added. Gas lowered.
22d	4:00 P.M.		Gas increased.
22d	10:36 P.M.		Commenced tapping. Heat No. 90,502. No. 3.
22d	10:50 P.M.		Tapping complete. Gas still on.
22d	12:15 A.M.		Gas off. Making bottom.
22d	12:57 A.M.		Bottom made. Gas on again.
23d	1:00 A.M.		Commenced charging. Heat No. 90,503. No. 4.
23d	2:30 A.M.		Gas increased.
23d	2:40 A.M.		Scrap charged.
23d	4:55 A.M.		Hot metal added. Gas lowered.
23d	4:00 A.M.		Charge completed.
23d	2:30 P.M.		Hot metal added.
23d	2:34 P.M.		Tapping commenced. Gas still high.
23d	2:50 P.M.		Tapping complete. Gas off. Bottom made.
23d	3:13 P.M.		Bottom made. Gas put on.
23d	3:38 P.M.		Commenced charging for heat No. 90,504. No. 5.
23d	5:55 P.M.		Charging complete.
24th	4:35 A.M.		Commenced tapping heat No. 90,504. No. 5.
24th	4:50 A.M.		Tapping complete. Gas still on.
24th	6:00 A.M.		Making bottom. Gas taken off.
24th	7:05 A.M.		Gas on again. Bottom made.
24th	9:30 A.M.		Gas increased.
24th	10:52 A.M.		Gas taken off again.
24th	10:56 A.M.		Gas put on again.
24th	11:00 A.M.		Charging commenced for heat No. 90,505. No. 6.
24th	1:37 P.M.		Hot metal added. Gas lowered.
24th	1:45 P.M.		Charging complete. Gas increased.
24th	10:20 P.M.		Tapping commenced. Gas off. Bottom.
24th	10:30 P.M.		Tapping complete. Gas off. Bottom.
24th	10:38 P.M.		Bottom made. Gas on again.
24th	11:45 P.M.		Commenced charging for heat No. 90,506. No. 7.
25th	2:10 A.M.		Charging complete.
25th	2:45 A.M.		Gas increased.
25th	4:15 A.M.		Gas increased.
25th	4:55 A.M.		Gas decreased.
25th	9:27 A.M.		Commenced tapping heat No. 90,506. No. 7.
25th	9:35 A.M.		Tapping finished. Gas off. Making bottom.
25th	9:50 A.M.		Tapping and bottom made. Gas on again.
25th	10:05 A.M.		Charging commenced for heat No. 90,507. No. 8.
25th	11:20 A.M.		First charge complete.
25th	11:15 P.M.		Charging complete.
25th	11:40 P.M.		Hot metal added. Gas still high.
25th	11:52 P.M.		Finished tapping. Gas still on. No. 8.
25th	12:00 A.M.		Making bottom. Gas off.
25th	12:53 A.M.		Bottom made. Gas put on again.
26th	2:23 A.M.		Commenced charging heat No. 90,508. No. 9.
26th	4:20 A.M.		Charging completed. Gas increased.
26th	1:54 P.M.		Commenced tapping heat No. 90,508. No. 9.
26th	2:06 P.M.		Tapping finished. Gas off. Bottom.
26th	2:36 P.M.		Bottom made. Gas put on again.
26th	2:39 P.M.		Commenced charging heat No. 90,509. No. 10.
26th	4:15 P.M.		Finished charging.
27th	1:07 A.M.		Commenced tapping No. 90,509. No. 10.
27th	1:15 A.M.		Finished tapping.
27th	1:32 A.M.		Making bottom. Gas off.
27th	2:02 A.M.		Bottom made. Gas on again.
27th	2:09 A.M.		Commenced charging No. 90,510. No. 11.
27th	4:48 A.M.		Hot metal added. Gas lowered.
27th	4:52 A.M.		Gas increased.
27th	12:35 P.M.		Commenced tapping No. 90,510. No. 11.
27th	12:52 P.M.		Tapping, etc., completed.
27th	12:58 P.M.		Producers down end of test.

TIME PRODUCERS WERE OFF FOR CLEANING

DATE	PRODUCERS	No. 1	2	3	4
21	Minutes	25	30	40	25
				70	
22		30	35		35
23		30	30	50	30
24		55	35		30
25		55	35	55	30
26		60	10	55	
27					30

It will be noted in the table for steam consumed that a total figure for steam blown is obtained, this being the figure that is often used in gas producer testing. When the producers are operating at one-half, one-fourth, or no load, less steam

STEAM BLOWN

TEST OF 161 HOURS, 32 MINUTES, ON FOUR PRODUCERS AND TWO FURNACES

Furnace	Charging	Working	Hot Metal	Tapping	Patching	Waiting on Material

No. 89	23° 33'	106° 26'	1° 19'	2° 33'	8° 29'	19° 12'
No. 90	33° 22'	92° 12'	1° 17'	2° 15'	6° 11'	26° 36'

Steam nozzle, 0.4375" diameter, hence 0.1500 square inches area.
Average gauge pressure when working = 45 pounds. = 60 lbs. absolute
Steam per minute per producer = (Area $\times$ Abs. P. $\div$ 70) $\times$ 60 = 7.713 pounds
Total steam, no delays, for four producers for 161° 32' = 299,018 pounds

Delays:
Equivalent of one producer off cleaning for 15° 10' = 7,019 pounds
Equivalent of two producers off when patching. 14° 40' = 13,575 pounds
Gas on $\frac{1}{2}$ when adding hot metal. 2° 36' = 1,805 pounds
Two producers at $\frac{1}{2}$ steam for 45° 48' = 21,195 pounds
Two producers at $\frac{1}{2}$ steam for 56° 53' = 13,168 pounds

Total. 56,762 pounds
Steam used during the test = 299,018 - 56,762 = 242,256 pounds

is used and in direct proportion to the gas used, hence the above deductions, giving the net quantity of steam consumed.

TABLE NO. 1

	Per Cent.	Weight, Pounds	Per Ton of Coal	Per Ton of Ingots, 1615
Coal charged	100.00	856,000	2,240	530 pounds
Ash loss	5.65	48,360	126.5	29.93
Coal lost in ash	1.07	9,160	23.9	5.65
Coal lost in soot	.69	5,906	15.4	3.64
Total coal loss	1.76	15,066	39.3	9.29
Moisture	1.11	9,500	24.8	5.86
Coal gasified	98.24	840,934	2,200.7	520.0
Carbon in coal gasified	76.23	641,000	1,677.5	396.0
Carbon in gas, per cubic foot		(0.010802)		
Cubic feet gas made		59,340,000	155,290	36,740 cu. ft.
Pounds of gas made		4,219,000	11,040	2,612 pounds
Steam blown		242,256	654	150.3
Air blown		3,353,180	8,775	2,075

Table I shows the distribution of carbon from the coal in the gas made and in the refuse produced in the process. This table shows the distribution per ton of coal and also per ton of ingots made, and is taken from test conditions, and during this test some 530 lb. of coal were required per ton of ingots made. Since it is desired to have this heat balance figured for strictly operating conditions, the figure 510 lb. of coal per ton of ingots is taken, this being an average figure, and the results figured accordingly. Table II is thus figured from the results obtained from a test, and from which the conversion of one ton of coal into gas is obtained, and these figures used in obtaining the distribution for the rate of 510 lb. of coal per ton of ingots made.

TABLE NO. 2

	Per Cent.	Weight	Per Ton Coal	Per Ton Ingots
Coal charged	100.00	829,000	2,240	510 lbs.
Ash loss	5.65	46,840	126.5	28.8
Coal loss in ash	1.07	8,870	23.9	5.5
Coal loss in soot	.69	5,720	15.4	3.5
Total coal loss	1.76	14,590	39.3	9.0
Moisture	1.11	9,200	24.8	5.66
Coal gasified	(98.24)	814,410	2,200.7	501.
Carbon in coal gasified	(76.23)	620,800	1,682.4	381.7
Carbon per cubic foot of gas		0.010802		
Cubic feet of gas made		57,100,000	155,100	35,310
Pounds of gas made (dry)		4,081,000	11,028	2,510
Steam blown		242,256	654	149.
Air blown		3,289,000	8,888	2,024

Following is the analysis of the coal. The proximate analysis is representative of that obtained in the laboratory. Some difficulty was experienced in obtaining the ultimate analysis, especially considering the hydrogen, but the ultimate analysis here given is obtained by Dr. Parr's method and the hydrogen content assured of.

ANALYSIS OF COAL

Proximate Analysis		Ultimate Analysis of Volatile	
Volatile matter.....	34.94%	Carbon.....	17.93%
Fixed carbon.....	58.30%	Hydrogen.....	5.02%
Total carbon.....	76.23%	Nitrogen.....	1.38%
Ash.....	5.65%	Oxygen.....	10.61%
Moisture.....	1.11%	Total.....	34.94%
Combustible in ash.....	15.13%		
Pure coal.....	93.24%		
Coal lost in the ash. Pure coal = 93.24%		True ash.....	= 84.87%
Ash.....	= 5.65%	Combustible.....	= 15.13%
Moisture.....	= 1.11%		
Refuse produced in burning coal. 5.65 + 84.87% = 6.65%			
6.65 - 5.65 = 1.00 = Combustible. 1.00 + 93.24% = 1.07%			
1.07% = Coal lost in ash.			

Approximate Analysis of Ash, Estimated

Fe.....	= .85
S.....	= 1.16
SiO ₂	= 1.54
CaO.....	= .80
Al ₂ O ₃	= 1.30
Total.....	= 5.65%

In the following analysis of gases, the gases are figured at 32 deg. F., and not at 62 deg. F., as is common practice, for the reason that figuring at 32 deg. F simplifies the transfer to the metric system. It would be a great advantage in many calculations if 32 deg. F., and not 62 deg. F., were taken as the standard temperature for measuring gases.

Having figured the fuel down to a working basis, thereby obtaining the heat available and the losses in the making of the gas, it is necessary to similarly treat the materials charged into the furnace. On account of the numerous chemical reactions involved it is necessary to compile an "elementary distribution," with the object in view of their final distribution and arrangement in the metal, slags, and gases. Accordingly, the following analyses have been taken as representative of the materials charged, and for the object in view have been adjusted to read 100 per cent, since no laboratory analyses are reported as totaling 100 per cent.

OPEN HEARTH. ANALYSIS OF RAW MATERIALS

The following temperatures are the results of averaging many observations, and can be taken as representative of the temperatures met with in the parts of the furnace quoted. This table also shows the efficiency of the producers and the regenerators, which figures are obtained in the heat balance which follows.

SUMMARY	
MATERIALS USED PER TON OF INGOTS PRODUCED	
Producer Gas:	
Coal.....	510.00
Steam.....	149.00
Air.....	1,995.50
H ₂ O (air).....	28.50
H ₂ O (coal).....	5.60
Gas made (dry).....	2,510.00
H ₂ O (gas).....	72.00
Hot gas efficiency of the producers.....	94.99%
Efficiency at delivery to the regenerator en- trance.....	91.77%
Temperature of gas regenerator.....	2,120°F.
Temperature of gas coming from regenerators.....	1,940°F.
Temperature of gas going to regenerators.....	1,100°F.
Pounds of air required for combustion of pro- ducer gas.....	7,378.00
Moisture in this air.....	100.00
Temperature of air regenerator.....	2,260°F.
Temperature of air going to regenerator.....	905°F.
Temperature of air coming from regenerator.....	2,012°F.
Efficiency of the regenerators.....	79.22%
Reversals on No. 90 Furnace, during the week's test:	
Total number during week.....	= 509
Average time.....	= 19 0 minutes
Longest time.....	= 70 0 minutes
Shortest time.....	= 2 0 minutes
Temperature of steel running from furnace.....	= 3,012°F. temperature of steel
Temperature of burned gases at end of furnace.....	= 2,832°F.
Temperature of gases just outside regenerators.....	= 1,252°F.
Temperature of stack.....	= 1,200°F.

final arrangement in the metal, slags, and gases. It will be noted that a run-off slag is first produced, then a normal slag, a portion of which normal slag goes into the ladle to help make up the ladle slag.

The above Table IV on the producer gas is here given to show the distribution of moisture. It will be noted that there is an increase of 1 per cent in the amount of moisture carried in the producer gas after it has passed the reversing valve. Reversing valves, in nearly all cases are water cooled, and the hot producer gas coming in contact with a water seal naturally picks up a quantity of moisture, which throws a large portion of sensible heat that was of service into latent heat that cannot be used. Does not this increase in moisture, and the accompanying decrease in the effective heat delivered to the furnace, permit of the suggestion that reversing valve design might be improved, with the use of other material, such as tar, as a sealing fluid?

On account of the importance of the flue gases, Table V is here printed. This table shows the analysis obtained theoret-

TABLE V FLUE GASES				
Analysis		By Weight		
Gas	Test	Check	Wet	Dry
CO ₂	16.082	16.730	Oxygen	21.967
CO	0.135	0.140	Carbon	4.200
O ₂	11.476	7.930	Nitrogen	68.330
N ₂	72.307	75.200	Moisture	5.514
		Pounds dry gas	10,004	
		Pounds H ₂ O	584	

In all the calculations it has been necessary to consider the moisture present in the materials used and the gases formed. The heat taken out by the moisture, superheated to the high temperatures involved amounts to a large figure, and is an important part of all the calculations. It will be noted in the analysis of the raw materials charged that soft ore runs as high as 20.26 per cent moisture. Economy would be obtained by drying such material before charging.

Table VII gives the pounds of materials used in the production of one ton of ingots, together with the quantities of slags and gases produced.

In the figuring of the heat balance, which follows, the figuring is based on heat per ton of ingots.

The above table would also be of value in open-hearth furnace design, when considering the gases used and formed.

Table VI gives in a condensed form the arrangement of the

various materials in pounds, giving the amounts of material charged, slags formed, and steel produced, and from which table an adjustment of the oxygen was obtained. That is the amount of oxygen freed, and the amount of oxygen absorbed in the various reactions, together with the oxygen coming into the furnace from the gas mixture, gives the amount of free oxygen that enters into the burned gases passing out of the furnace.

All data taken for the figuring of the heat balances are operating figures such as are found in practice, since test conditions are often in error when taken as representing average practice.

The following heat balance naturally divides itself up into many parts, and for this reason on the left-hand side of each sheet appears the data and results in obtaining the heat involved at each stage of the process, while on the right-hand side of the sheet is printed the calculations involved in producing the result.

In the calculations effecting the heat balance the methods employed are those of Prof. J. W. Richards, as given in his most valuable work, "Metallurgical Calculations." Figures used in obtaining the mean specific heat of the materials involved, and symbolized SM, are those constants given by Dr. Richards. These constants for the different materials and elements are, in nearly all cases, figures for the specific heat at 0.0 deg. C., or 32 deg. F.; hence for obtaining the specific heat at a higher temperature the figure at 32 deg. F. is increased by the addition to this figure of the product of a known constant and the temperature range. The results are given in detail in the calculations.

In figuring the latent heat in gases due to the moisture content, the metric system, as given by Dr. Richards, is used, and the result obtained in kg. cal. converted into B.T.U.

In collecting the data it was very difficult to obtain any reliable information in relation to the moisture contents of air and gas, but the figures as here given were checked a number of times, and accordingly can be taken as representative of the conditions met with in the regenerator cellars in open-hearth plants.

It will be noted that the hot gas efficiency of the producers' figures out to be 94.99 per cent, and that the loss of heat after passing the reversing valves amounts to 3.22 per cent, so that the net efficiency of the producers delivering gas to the furnace regenerators is 91.77 per cent. The gas flues on the furnaces tested were underground, and the question naturally comes up: Would there be as great a loss of heat if the flues were carried overhead and not buried as in this case?

In the foregoing calculations it will be noted that the gas producers were taken as a separate unit in the amount of heat produced, and which likewise follows for the air required for the combustion of this gas. The heat in the cold materials as charged into the furnace is also considered since the normal temperature of this material is considerably above 32 deg. Fahrenheit. The heat due to oxidation of the carbon, silicon, and other ingredients in the metal by the iron ore charged is also treated separately, as it may be noted in the calculation.

The summary of the above calculations is as per the following table, which gives the total heat which is delivered to, or produced within the furnace, and the sum total of which gives the first part of the heat balance. The distribution and utilization of this heat is as per the calculations which follow.

Radiation in flue.....	287,373	2.25
Loss up stack.....	3,865,350	30.32
Total.....	12,747,054	100.00

From the above heat balance it will be noted that the amount of heat actually used in the melting of the steel amounts to but 10.11 per cent of the heat in the fuel, and the total amount of heat used in performing useful work is 18.91 per cent, that is, the efficiency of an open-hearth furnace, giving the furnace credit for reduction, slag formation, and melting metal, is less than 20 per cent. There are a number of ways of utilizing the waste heat from the furnace, one of which is the utilization of waste heat boilers connected to the stack. Aside from this, and considering the furnace as a heating unit, there is great room for improvement in the furnace itself.

In modern boiler houses and engine rooms there are gauges, etc., giving information as to the working of the apparatus, and in many plants there are steam engineers that make regular use of the indicator as a guide to engine performance, but the use of gauges, etc., in the open hearth, has unfortunately not met with a favorable reception. Some plants have meters on their gas lines to each furnace, but this is the exception and not the rule, and where the meters are applied they are on natural-gas furnaces.

The value of having a recording mechanism on a furnace may be noted from the following. On one of the furnaces from which this heat balance was figured, there were 509 reversals for the week. The average time for each reversal was 10 minutes, the longest period on one set of regenerators was 70 minutes, and the shortest period was 2 minutes. In open-hearth practice it is the custom for each turn to keep up one end of a furnace. That is the night shift might have the left end of a furnace and the day shift might have the right end of a furnace to keep up. One turn naturally favors its end of

the furnace, and in the operation of the furnace will do all that it can to favor its side and keep it from cutting away, thereby placing all the wear and tear on the other end, as the case may be.

This practice leads to irregularity in the operation of the regenerators, and soon there is a good and a bad end to the furnace. The adjoining illustration shows the difference in time involved in the reversals. A long period and then a short period on a regenerator naturally does not give a proper distribution of heat to the regenerators, and one set of regenerators will be at a lower temperature than the other. At certain periods in an open-hearth heat it is necessary to have quick reversals, but there is no reason why these reversals

should not and could not be made of equal duration for each set of regenerators, thereby maintaining them at a balanced temperature.

If it were the practice to have all furnaces equipped with a recording mechanism which would show the reversals, the superintendent would be aware of what took place at all hours, and, by paying more attention to the utilization of heat in a furnace, would have a very good opportunity to effect economy.

The above heat balance was for a set of two furnaces of 60 tons capacity, with a hearth 32' 0" x 14' 9", such a 60-ton furnace showing an efficiency of 18.91 per cent.

There is a wide discrepancy in open-hearth design, as may be noted by the following.

Plant.....	Capacity.....	Hearth.....
Duquesne.....	60 Ton.	32' 0" x 14' 0"
Ohio Works.....	60 Ton.	29' 0" x 14' 11"
Gary.....	60 Ton.	40' 0" x 15' 3"
Republic.....	60 Ton.	32' 0" x 15' 0"
Lackawana.....	60 Ton.	43' 0" x 16' 0"

There is an even greater variation in the dimensions of the regenerators, flues, etc., in the above furnaces than there is in the hearth, hence it would follow that the utilization of heat would be different, and it would be profitable to all steel manufacturers to know just what design would be the most effective for the result desired. The logical way to determine this is from a metallurgical standpoint, which in this case would be in heating efficiency.

Pittsburgh, Pa.

Rational Absorption of Hydrochloric Acid*

By Dr. Theodor Meyer

Whoever tries to acquaint himself with the methods and apparatus for the production of muriatic acid from hydrochloric acid gas and reads the chapter of more than 100 pages in Lunge's great treatise may easily have the sensation of wheels turning in his head, as said by the scholar in Goethe's "Faust." Surely, I do not want to depreciate Lunge's excellent work as the completeness and critical exactness of his exposition of the subject can hardly be surpassed. But the processes and apparatus discussed by him are of such a variety, the propositions and views even partly contradictory and often irrational, that much acumen and care is necessary to discover what is suitable and rational in the chaos.

As Lunge shows, even Hurter's writings and experiments based on sound science and on practical experience contain many errors and lead in part to wrong conclusions such as might not be expected from an expert like Hurter. A point in question is, for instance, the representation of the coke tower as the most excellent condensation apparatus. The acme of absurdity is the "invention" of Schloesing, who finds pre-cooling of the gases to be detrimental and concludes that to

sorption of hydrochloric acid is the content of HCl in the gas, apparatus for the production of muriatic acid from hydrochloric acid gas and reads the chapter of more than 100 pages in the gas mixture.

These two laws are the essential basis of the rational absorption of hydrochloric acid. They are illustrated by the curves in Fig. 1 which have been plotted according to the formula of Hurter:

$$C = (0.3040 - 0.0016 t) P^{0.18}$$

in which C is the grams of HCl absorbed by 1 gram of water at the temperature t and P is the partial pressure of the HCl gas in millimeters of mercury.

The most important rule which may be deduced from these curves for the requirements of practice is to keep the concentration of HCl in the gas mixture at not less than 20 or 30% if possible.

Besides the above considerations a number of other points must also be considered, especially the influence of the diluting air on the heat phenomena and the content of water in the gas mixture; the effect of cooling on the water precipitation by which latent heat is again set free; the speed of the gas; the impurities in the gas; the relation of hydrochloric acid of different concentration on the excess of air, and finally the particular properties of the materials used for the apparatus.

Above all it is clear that a good and quick absorption of the HCl can only be accomplished by most intimate contact of the gas with water. This contact may be provided in general by three methods which are different in principle.

(1) The gas is subdivided into very small bubbles and is passed through the water by pressure or suction.

(2) The water is subdivided into exceedingly small droplets and made to act on the gas.

(3) As large a liquid surface as possible is provided to be acted on by the gas.

The method (1) is useful in the laboratory, but is not suitable for manufacturing on a large scale, since if the depth of the liquid is low the gas bubbles pass through it too quickly, so that there is not sufficient time for an intimate contact. On the other hand, if the depth of the liquid is great a rather considerable amount of work would be required for the gas to overcome the pressure of the liquid.

The method (2) was discussed unfavorably by Hurter in 1893 (*Journal Society Chemical Industry*, page 226). His criticisms were justly refuted by Lunge, though they could be understood since the patented process of Newall and Bowman of 1874 had not proven successful. But two points must be taken into consideration in explaining this lack of success. Firstly, at that time no direct means had yet been evolved to subdivide liquids into such a very fine spray as is possible to-day. Secondly, Newall and Bowman tried to apply the method in a wrong manner. It is well known that muriatic acid with more than 25% HCl loses HCl when in contact with air at a temperature of 15° C. (59° Fahr.) and this loss of HCl is, of course, the quicker the more intimate the contact with the air. As the temperature increases that strength of acid which will remain constant in the presence of air is still further reduced. For instance, at 60° C. (140° Fahr.) it is 23% HCl. This shows that muriatic acid of at least 32% (20° Baume) could be obtained by means of a water spray only if the HCl concentration in the gas is correspondingly high.

But, even in this case, trouble is caused by the heat of absorption which manifests itself the more, the less diluent gases are present which could take it up. These two points were not sufficiently taken into consideration by Newall and Bowman. As they carried out the process the spray of water acted directly on the gases coming from the furnace and this reaction took place in sandstone vessels which were connected by means of stoneware pipes, so that there was little opportunity for the escape of the heat evolved. We will show later that the use of spray water can give very good results if it is applied in the correct way and at the correct place.

The method (3) is the one which is being generally and almost exclusively used at present, although details of operation

FIG. 1.—ABSORPTION CURVES FOR DIFFERENT GAS CONCENTRATIONS AND TEMPERATURES

aid the absorption of the gases their temperature and vapor pressure should be as high as possible.

It is well known that the absorption of hydrochloric acid is an exothermic reaction. According to Berthelot when x grams of HCl are dissolved in a gram of water $477.5x - 157x^2$ calories are produced; for instance, the heat evolved in the formation of hydrochloric acid of 20° Baume corresponds to a rise of temperature of 118° C. (242° Fahr.). It is therefore evident that the absorption will be easier and quicker the better means are provided to carry off this newly produced heat.

But the maximum concentration of the hydrochloric acid produced also depends on the temperature. For instance, when the hydrochloric acid is absorbed from the gas of 5% concentration at 20° C. (68° Fahr.) it is still possible to produce acid of standard concentration (32% HCl), while at a temperature of 50° C. (122° Fahr.) a higher concentration than 28% cannot be obtained. On the other hand, at 5° C. (42° Fahr.) a concentration of almost 34% can be obtained. According to Hurter's calculations, at a temperature of t ° C. one gram of water is able to absorb $0.3040 - 0.0016 t$ gram HCl.

The second most important factor which determines the ab-

*Translated from *Zeitschrift für Angewandte Chemie*, February 21, 1913, p. 97.

vary greatly and apparatus of greatly different forms are employed, such as towers with coke filling or stoneware filling, Lunge plate towers, stoneware vessels, and stoneware tourills, and Cellarius cooling and absorption vessels.

In England, the mother country of the manufacture of hydrochloric acid, the big coke towers in connection with some stoneware vessels have remained chiefly in use. On the other hand, in continental Europe stoneware tourills with a final washing tower of stoneware of moderate dimensions are pre-eminent. The Schaffner (Aussig) system with towers of 8 to 12 meters (26 to 40 feet) height filled with stoneware dishes are in particular favor.

The large coke towers, which have a height up to 36 meters (120 feet), are generally built of sandstone, so that there is little chance for the air to produce a cooling action. If the uncooled gases enter such a tower at the bottom a moderate cooling effect is obtained by the evaporation of the muriatic acid trickling down from above so that the heat becomes latent and as such is returned to the higher portions of the tower where condensation takes place and the latent heat becomes free again, while the condensed acid trickles down again, evaporates partly anew and so on.

The net effect of what happens is, therefore, that the heat is transferred to a somewhat higher point, while the real condensation process is restricted to the highest and coolest part.

The hydrochloric acid formed in the highest and coolest part of the tower must, therefore, pass through the lower hot portion, and as the constant concentration of muriatic acid at the boiling point is not more than 20% or 13° Baume, it is evident that it is very difficult to get in this way a fairly high concentration of the acid.

Moreover, in many cases the tower is not even able to reduce the concentration of HCl in the exit gases to the desired degree, so that it becomes necessary to pass the gas finally through a washing tower and the low acid obtained from it is a source of trouble.

Formerly the hydrochloric acid was used principally for the Weldon process, especially in England, and for this purpose a concentration of 16 to 18° Baume was sufficient. At present the conditions have been changed, especially in continental Europe, where the Weldon process has been replaced almost completely by the electrolytic process. To have a commercial value, hydrochloric acid should have at present a concentration of not less than 20° Baume, and for some purposes, like the manufacture of aniline salts, a considerably higher concentration, up to 24° Baume, is required.

The system of a number of tourills with a final washing tower, which is used largely in Germany, is undoubtedly superior to the large coke tower, since part of the sensible heat and of the heat of absorption is carried off in advance by the tourills with their relatively large outside surfaces and since the rather thin stoneware walls of the tower carry off far more heat than the sandstone walls in the British system, which are six times thicker.

Nevertheless, even in the German system about one-half of the absorption still takes place in the towers, especially if the inaccessible surface of the liquid in the tourills becomes covered with fatty impurities. This trouble occurs often when some oil or grease is put into the saltcake pan to prevent ebullition. In such cases a failure of the tourills often occurs and it may happen that in order to get the acid up to 20° Baume it must flow off at 15 to 17° Baume from the tower and that the tower becomes so hot as to crack the walls. In a system designed in a rational manner with pre-cooling and cleaning of the gases the acid flowing off from the tower has a concentration of only 1 to 2° Baume.

Effective pre-cooling cannot be obtained with air, especially with chemical stoneware as the only material that is really to be taken into consideration a wall-thickness of 10 to 15 millimeters (0.4 to 0.6 inch) must be used. The specific heat of water is four times that of atmospheric air if figured per weight, and more than 3,000 times that of atmospheric air if figured per volume.

After Fryer and others had made unsuccessful experiments, water-cooling was successfully introduced in connection with the invention of the absorption vessel of Lehmann and Cellarius in 1899, although their absorption vessel was originally not intended for water-cooling and could not be used with water-cooling (*Angew. Chem.*, Vol. 21, page 1069, 1908). When in 1901 I had to solve the problem to get hydrochloric acid of 21° Baume from the gas of the Oehler muffle furnace, I tried to employ the new Cellarius absorption vessel by modifying its construction for water-cooling. The success was excellent.

The gas coming from the furnace, after having been cooled to air temperature by passing it through 11 empty water-cooled vessels, was passed through a system of 35 absorption vessels placed in water circulating in the opposite direction. In spite of pre-cooling and absorption cooling, a rise of temperature up to 80° C. was still obtained. This occurred approximately in the twelfth vessel and proves the intensity of the absorption. The acid running off from the front vessel could easily be obtained with a concentration 23.5 to 24 or even 24.5° Baume. This concentration changed, of course with the fluctuations in the concentration of the gas, which amounted to about 40%.

If the maximum temperature is displaced toward the exit, this should be taken as a warning to restrict the water supply somewhat. It is thus possible to control the operation of the absorption process with this type of apparatus by means of a few thermometers, which is much simpler than the measurement of the specific gravity, although the latter may also be observed in a convenient manner.

After having been passed through the water-cooled vessels the acid was passed through a few air-cooled vessels and then through a washing tower, which yielded an acid of 1.5° Baume when supplied with pure water.

In 1902 C. Uebel devised a vessel similar to the Cellarius tourill which is, however, not intended for circulation of liquid through it, but especially for cooling of gases and vapors, for instance, in nitric acid manufacture. In order to distinguish it from the Cellarius absorption tourill it might be properly called a condensation tourill. It is being used now generally for pre-cooling the hydrochloric acid gases which it robs of their sensible heat and latent heat, while the Cellarius absorption tourill takes away the heat of absorption while it is being formed.

In the course of time several more or less different forms of vessels have been designed, which, however, have no advantages over the original patented construction. Yet it cannot be claimed that the Cellarius tourill already satisfies all requirements.

In an ideal absorption vessel the gas and the liquid should act on each other in counter-current. Since the absorption makes the liquid heavier the liquid should enter at the top and leave the vessel at the bottom. In the Cellarius vessel, however, the liquid enters and leaves at the bottom. Further, the liquid should enter where the gas goes out and the liquid should flow off where the gas enters. In the Cellarius vessel, however, the liquid enters and leaves alternately at the entrance and exit of the gas. The liquid, therefore, circulates in one-half of its vertical as well as horizontal passageways only in counter-current with the gas, and in the other half flows in the same direction as the gas.

Moreover, an effective counter-current arrangement is rendered difficult by the shortness of the passageway of the gases, which, measured between the centers of the gas inlet and the gas outlet, is only 50 centimeters (19 inches) for size I and 70 centimeters (28 inches) for size II.

This short length of the Cellarius vessels has another disadvantage. The front side of the vessels should be accessible by means of a passageway, say 1 meter (3.3 feet) wide, while the width of two rows of tourills with their ends placed against each other is 225 centimeters (7½ feet), including cooling boxes for size II, so that almost one-third of the floor space of the building is required for the passageways.

Finally, it cannot be denied that the form of the Cellarius

tourill is a little complicated, or at least that a simpler form could surely be made at less cost.

The design shown in Fig. 2 is intended to realize the advantages of the Cellarius tourill while avoiding its disadvantages. The gas passes here in the ordinary manner from the back to the front of the absorption vessel, then from the front to the back in the next absorption vessel, and so on. The passage way of the gas in each vessel is 140 centimeters (55 inches). The gas and the liquid are always in counter-current, since the liquid also enters the suc-

FIG. 2.—ABSORPTION VESSEL FOR HYDROCHLORIC ACID

cessive absorption vessels alternately at the front and at the back. The liquid always enters near the surface and leaves at the bottom. As these absorption vessels are 160 centimeters (63 inches) long, hardly one-fourth of the floor space of the building is required for the passageways. On account of their simple form the manufacture of these absorption vessels involves no difficulties.

An advantage of the Cellarius vessel is the quiet surface, which is due to the fact that the liquid enters and leaves below the surface. The minimum height of the level of the liquid is the height of the saddle. Since my new absorption vessel has no saddle, it might seem that the level of the liquid could not be maintained properly. However, it is easy to see that the level depends entirely upon the drop from the exit from one vessel to the influx into the next vessel, or in case of the last vessel, upon the inclination of the exit pipe. If the vessels are properly arranged with a descent of 10 to 15 millimeters (25/64 to 19/32 inch) from one vessel to the next vessel, it is easy to adjust the level of the liquid so that it is a few millimeters above the influx.

In one respect the quiet surface of the liquid is liable to become a source of trouble. If the gas is not free from particles insoluble in water and if it contains especially fatty particles, these are liable to form a film on the surface of the liquid so as to prevent absorption. When this happens it is easily observed by the fact that the vessel is cool. Even when using pure materials this was found to happen, and the cause of the trouble was discovered to be a film of a white substance like paraffine, which seemed to have had its origin in the rock salt. By means of a gas filter such troubles can be avoided with certainty.

Instead of two gas inlet and outlet pipes three or four may be easily attached to each absorption vessel, if this is desirable for the distribution or the mixing of gases. If the vessel is intended to serve for condensation only, the only change necessary is to omit or to close the upper pipe for the entrance of the liquid. The same vessel may, therefore, be used for absorption as well as condensation.

While an extended quiet surface of the liquid is most suitable for the production of a strong acid it is by no means suitable for extracting the acid from dilute gases, which becomes necessary at the finish of every condensation process.

At that point it is proper to use a finely sub-divided spray of water or dilute acid whereby a most intimate mutual contact can be obtained without danger of reducing the efficiency by the excess of air or by the heat of absorption, which is hardly noticeable in this case.

In the following I give comparative data for both types of absorption vessels, the figures of the Cellarius tourill referring to size II.

Cellarius Tourill II.	New Absorption Vessel.
Length 103 cm., or 40 in.	160 cm., or 63 in.
Width 66 cm., or 26 in.	55 cm., or 22 in.
Total Volume	
110 liters, or 29 gallons.	173 liters, or 45.7 gallons.
Liquid Volume	
40 liters, or 10.6 gallons.	88 liters, or 23 gallons.
Gas Volume	
70 liters, or 18.5 gallons.	85 liters, or 22.5 gallons.
Absorption Surface	
0.55 sq. m., or 6 sq. ft.	0.88 sq. m., or 9.5 sq. ft.
Cooling Surface	
1.4 sq. m., or 15 sq. ft.	2.3 sq. m., or 25 sq. ft.

Since only above 24 to 25% muriatic acid loses in concentration by contact with air it might appear practical at the first glance to carry out the absorption process by means of a spray of water up to that limit and to absorb only the balance by means of a quiet surface of water. But this would be a mistake. Firstly, because the absorption apparatus for spray liquid cannot be easily constructed for water-cooling and, secondly, because the spraying requires power, which means an extra expense.

So far the absorption of the last traces of acid from the gas has been always carried out in washing towers as far as possible. Undoubtedly, in a tower there is a much more intimate contact between the gas and liquid than in vats or tourills, but not nearly as intimate a contact as in spray apparatus.

Experiments made on a large scale have given, for instance, the following figures for the concentration per cubic meter: before the spray cylinder 56 grams HCl, 1.9 grams SO_2 , 3.5 grams SO_3 , and behind the spray cylinder 2.2 HCl and 28 grams ($\text{SO}_2 + \text{SO}_3$) figured as SO_3 .

The final washing tower is in a sort of an intermediate position and has, therefore, no right of existence whatever for the absorption of hydrochloric acid. Where the object is to get the last traces of acid from the gases and to enrich the dilute acid thereby obtained up to a

FIG. 3.—SPRAY APPARATUS

concentration of 4 to 6° Baume the most preferable procedure is to use water spray process and to circulate the obtained dilute acid directly through the absorption vessels in order to bring it up to the concentration which can be obtained with the acid concentration prevailing in the gas.

In conjunction with the Deutsche Ton- und Steinzeugwerke

in Charlottenberg* I have designed an apparatus for the treatment of dilute hydrochloric acid gas with spray water.

The principles of this apparatus for which a patent has been applied is based on the following:

(a) The gas and the spray of water are to be brought into as intimate contact as possible so that the gas is "hydratized," if we may use this expression.

(b) There should be no "dead corners" where there is no reaction, nor should the gas have any opportunity to avoid in part the action of the spray of water.

(c) The gas should be brought in a very slow and uniform current in contact with the spray of water.

(d) The spray of water should be in excess.

For this purpose the pipes through which the gas enters and leaves the apparatus are arranged in a tangential direction, the one at the conical or hemispherical top of the apparatus, the other at the bottom, while the spray nozzle yielding or emitting the water spray is best placed in the center of the top. (Fig. 3.)

The capacity of the nozzle is chosen in such a way that it gives almost the whole, but a little less than the whole quantity of the water which is necessary for recovering the HCl from the furnace in form of muriatic acid of the desired concentration. The hydrometer or thermometer readings determine the exact adjustment of the operation, which is carried out by supplying the small additional necessary amount of water directly into the last absorption vessel. The regulation of the acid concentration is, therefore, very much simpler than with the present concentration system with the final tower where it is necessary to ascend the tower in each case.

Especially with high coke towers this is very inconvenient. It should be pointed out that it is not sufficient as Lunge writes (*Handbuch*, Vol. II, third edition, page 375) to control the concentration of the finished acid several times during the day, for when this is found too low it is then too late to repair matters since the whole apparatus is filled with acid of too low a concentration. The daily measurement and adjustment of the supply of water to the tower is therefore absolutely necessary. This is, of course, also necessary whenever there is any change in the amount or number of the charges.

In the final tower (excepting, perhaps, Lunge's plate tower) about one-half of the volume is occupied by the filling material. For this reason and on account of its low efficiency it is necessary to make the tower high, several times higher than the spray apparatus. The lifting of the water to this height entails an expense which is practically as much as the expense for generating the pressure in the spray apparatus.

For towers of chemical stoneware the width is limited for constructive reasons, the maximum being about 1.4 meters (4.6 feet). Since about one-half of the cross-section in the same is taken up by the filling material, we have, with the spray apparatus of the same width, double the effective cross-section, while the velocity of the gas is reduced to one-half. However, the greatest advantage of the spray apparatus is the simplicity and cheapness of construction as compared with the final tower with its heavy foundation and high frame work and stairways.

According to the size of the hydrochloric acid plant and other circumstances one or more spray apparatus may be used and these may be connected in series or in parallel.

*The European Associates of the German American Stoneware Works.

It is advantageous to place behind the spray apparatus one or more gas filters, filled with granulated acid-resisting material, in order to catch the acid particles contained in the gases as mist (*Angew. Chem.*, Vol. 19, page 1313, 1906).

By using this new spray apparatus it is possible to recover the acid in a much more complete manner and to clean the exit gases in a much better way than heretofore. The acid is completely removed from the gas so that it is possible to let the gas pass directly into the atmosphere. It is not necessary to pass the gas into the smokestack, thereby greatly impairing the draft, so that it is necessary to build it higher.

The other rules which are to be taken into consideration for the absorption of hydrochloric acid, as well as constructive details, have been described by me elsewhere (*Th. Meyer, Sulfat und Salzsäure, Halle, 1907*).

I will, therefore, discuss only a few points bearing on the present subject.

The principle is essentially as follows: The more or less wet and hot gases, having been brought to a concentration as high as practicable, pass from the furnace with the least possible artificial suction into the pre-cooling apparatus. This consists of a preliminary empty vessel and a series of condensation tourills.

FIG. 4.—VERTICAL AND HORIZONTAL SECTIONS OF FINAL PART OF APPARATUS

At the beginning of this system a little water is added if necessary. The gases then pass through a stoneware exhauster and immediately afterwards through a gas filter; after having thus been purified and cooled, the gases enter into the series of water-cooled Cellarius tourills or absorption vessels of my approved design described above. (Fig. 3.)

They finally pass through one or more water spray apparatus and if necessary through a final gas filter. Fig. 4 shows the horizontal and vertical section of the final part of the apparatus.

With respect to the concentration of the hydrochloric acid gas, the apparatus for the decomposition of the sodium chloride by sulphuric acid is of chief importance. The reverberatory furnace which yields the most dilute gas is rarely found now, at least in Germany, but in the same class there are the gas from the Hargreaves process and the gas from the decomposition of magnesium chloride which is carried out on a commercial scale in the Stassfurt district, where the condensation of the HCl vapors is indeed very difficult.

The gas from the muffle is also very low in concentration. According to Lunge (*Handbuch*, Vol. II, 3 Aufl., pages 276 and 277) the average concentration was 1.3% HCl in one case and 2.6% in another case in the Chemische Fabrik Griesheim. According to the curves in Fig. 1 it is impossible

to get a 32% acid from such a gas, even if a very low temperature is employed such as is impractical on a commercial scale.

If the much richer gas from the pan which contains from 10 to 30% HCl would be mixed with the gas from the muffle a gas would be obtained from which acid of normal concentration could be obtained (although the concentration of the mixture would not be the arithmetical mean, since the volume of gas from the muffle is eight times that from the pan).

Usually, however, this mixing is undesirable, because pan acid and muffle acid are of different purity.

There is, however, another very simple way which is apparently little known; to bring the muffle acid up to 20 or 20° Baume. It is simply necessary to place the first one to the three tourills carrying the muffle acid in front of the absorption battery on the pan side. The pan acid is, of course, not connected into these tourills. I do not know if this easy way is used in factories.

It is certainly preferable to operate in advance with concentrated gases. I have worked on this problem for many years. The result has been on one side the Oehler furnace for bisulphate and on the other side the mechanical muriatic acid retort (German patents 186,398 and 238,570).

The mechanical retort requires sulphuric acid of approximately 90%, but the product of absorption is in proportion less impure.

With the Oehler furnace, consisting of several connected muffles, it is possible to get a gas containing 40 to 50% HCl in the average. With the retort it is possible to get an acid of 60 to nearly 100%.

If the retort is placed behind the Oehler furnace so that the firing of the Oehler furnace also serves for the retort and if the bisulphate coming from the Oehler furnace is further treated in the retort this combination represents a complete substitute for the ordinary saltcake furnace and besides other advantages it is able to yield a HCl gas of high concentration which can be easily condensed.

The pipes which conduct the gas from the furnace are liable to break pretty often, whether they are made of fire-clay, stoneware, glass or quartz. In order to avoid this it is advisable to insulate them well up to the point where they enter the pre-cooling apparatus, if it is not preferred to make them of sandstone.

Directly next to the preliminary vessel there is the battery of pre-coolers. In this combined system, as well as in the exhauster and the gas filter, so much impure acid is condensed as corresponds to the humidity and the temperature of the gas.

With the saltcake pan, the Oehler furnace, and also with the retort, the condensed acid amounts to 3 to 6% of the total acid. From the much more dilute and drier muffle gas not enough acid would be condensed; moreover, the muffle gas would enter the pre-cooling system at too high a temperature. For this reason a little water is added through the nozzle into the preliminary vessel, which must have for this purpose an inside height of 1.5 to 2.5 meters (5 to 8 feet). This water spray has a cooling action. Part of the heat is rendered latent and the water vapor thus formed is taken along to the center of the cooling system where it is condensed together with sulphuric acid and other impurities.

If the cooling system is arranged with cooling water running uniformly in counter-current so that it leaves the first vessel at a temperature of 80 to 100° C. (176 to 212° Fahr.) the gas may enter at a temperature of 200° C. without any danger of breaking.

The gas filter was first used in hydrochloric acid manufacture by Boulouvard (French patent 284,130, 1899), but at the wrong place, since it was placed directly after the furnace. But the gas filter can be efficient only when acting on the cooled gas. The particular object of the gas filter is to precipitate particles carried along in a misty form. Together with these acid particles the greatest part of the impurities is precipitated, especially sulphuric acid, iron chloride, etc., as well as some of

the arsenic. But the filter also serves to catch any fatty particles which would prevent the absorption.

One of the chief requirements of proper operation of the apparatus is the dimensioning of the pipes and of the draft. Stoneware pipes cannot be built like lead or iron pipes for any diameter. Hence the rule not to make the units of a hydrochloric acid plant too large.

Further, when designing a new plant, care must be taken to calculate as exactly as possible the quantities of gas which will be evolved per unit of time and to calculate from this the speed of the gas per second. The cooling action and condensation, as well as the absorption, depend, of course, under otherwise identical conditions, on the time required for working off the charge.

There are many sins committed against this principle especially with ordinary saltcake plants, in so far as tourills and towers of the same type and size are used for the absorption system of both pan and muffle and only the number of tourills connected in series (instead of in parallel) is sometimes somewhat larger for the muffle. In the illustrations of Lunge, for instance, figures 138 and 152, both the pipes for the pan gas and the muffle gas are exactly the same kind and, therefore, of the same cross-section.

As an example, let us take a large saltcake furnace in which 5,300 kilograms of sodium chloride are treated in 24 hours producing about 1,930 cubic meters HCl at 6° C., distributed as follows:

From the pan 1,160 cubic meters HCl = 5,800 cubic meters gas at 20% concentration at 0° C. = 8,560 cubic meters gas at 130° C.

From the muffle 770 cubic meters HCl = 38,500 cubic meters gas at 2% concentration at 0° C. = 62,580 cubic meters gas at 170° C.

Therefore the rate per second is as follows:

Pipe line from pan: 99 liters gas after the furnace = 66 liters after the pre-cooling system.

Muffle pipe line: 724 liters gas after the furnace = 447 liters after the pre-cooling system. If an internal diameter of 25 centimeters (9 $\frac{7}{8}$ inches) is assumed for the pipes carrying the cooled gas, we find a speed of flow of the gas of 1.37 meters per second in the pipes for the pan gas and a speed of 14.77 meters per second in the pipes for the muffle gas.

Even if, for the muffle gas, the pipes of 25 centimeters diameter should be replaced by pipes of 45 centimeters (18 inches) diameter (the largest which are available) the speed of the muffle gas would still be 4.55 meters per second, that is, three times the speed of the gas from the pan.

Pipes with a diameter of 45 centimeters (18 inches), however, can hardly be used between the Cellarius tourills, even if the largest size is chosen, since the gas inlets and outlets have a diameter of only 30 centimeters (11 $\frac{3}{4}$ inches).

There is, therefore, nothing left but to split up the absorption system for the muffle gas into two or more lines in parallel. For instance, for the construction of the gas filter, as made by the Deutsche Ton- und Steinzeugwerke according to my design, I always specify one filter for the pan and three in parallel for the muffle gas.

Even the best condensation apparatus cannot be maintained absolutely tight. Always a little air will enter and the more air will enter in the greater the suction. For this reason it is very important to maintain the draft not higher than is necessary.

The new spray apparatus can also be used in combination with the exhauster and gas filter advantageously for the auxiliary condensing system, the object of which is to avoid the escape of acid vapor during the operation when the furnace doors are open.

The dilute hydrochloric acid obtained in this way (for instance, in an Oehler furnace 3.7° Baume, 48% HCl, 0.24% H₂SO₄, and 0.007% Fe₂O₃), may be used even though not especially pure, as an addition to the main absorbing system so as to increase the total output of muriatic acid.

The great problem of the muriatic acid industry—the

mechanical furnace—is still a problem of the future and for the present there is little hope that it will soon be solved. But, even so, I trust I have shown that there are still many promising problems to be solved with respect to increasing the efficiency of operation in mechanical as well as hygienic respects.

Offenbach on Main, Germany.

An Electrolytic Theory of the Corrosion of Iron.*

By Bertram Lambert

The application of electrolytic ideas to the question of the corrosion of iron has been discussed by Whitney,¹ Cushman,² Tilden,³ Walker,⁴ Armstrong⁵, and many others, but much confusion and misunderstanding has arisen owing to the different interpretations used by the various writers.

The American writers have discussed the question from the standpoint of Nernst's conception of the source of electromotive force between a metal and a solution. It seems to follow from their reasoning that all iron (even if it be chemically pure and physically homogeneous) ought (a) to rust in contact with air (or oxygen), (b) to cause the deposition of copper from solutions of copper salts.

The present writer's experiments⁶ have proved beyond any doubt that iron can be prepared which will not rust on long exposure to air and water (either distilled or ordinary tap-water), and will not cause the deposition when placed in even strong solutions of copper sulphate or copper nitrate under ordinary conditions.

It also seems to be thought by many supporters and opponents of electrolytic theories that any electrolytic theory of the corrosion of iron must "stand or fall" on the question of the solubility of iron in pure air-free water.

The object of this paper is to show that a simple and natural development of the ideas of Faraday on electrolysis will give us the beginnings of a satisfactory theory of the corrosion of iron—a theory incomplete as yet owing to the lack of experimental facts, but one which is quite in accordance with well-established facts and which is not affected by the question whether iron is soluble to any appreciable extent in pure air-free water.

It is well known that while ordinary commercial impure zinc readily dissolves when placed in dilute sulphuric acid, the pure metal is scarcely affected unless metallic connection is made between it and another more electronegative metal, either within or without the liquid. Under these conditions the pure zinc dissolves, but the action ceases immediately the metallic contact between the pure zinc and the more electronegative element is broken.

In impure zinc the more electronegative element is already present within the mass of the metal, in the form of minute impurities, such as copper or lead, or perhaps, as another form of the metal which is relatively electronegative to the main mass of the metal.

Whenever we have two metals (or two modifications of the same metal) which are electrically different, that is, have different solution pressures, and they are placed in metallic contact in an electrolyte, then the relatively electropositive part will dissolve with the production of an electric current flowing through the electrolyte from the electropositive to the electronegative pole, and in the positive direction through the metal.

The rate of such a reaction depends: (a) on the magnitude of the difference of electric potential—that is, the difference of solution-pressure between the two metals or the two modi-

fications of the same metal, and (b) on the resistance offered by the electrolyte to the passage of the electric current.

No part of the metal can dissolve unless an electric current actually passes through the electrolyte. The rate of the reaction may, however, be so infinitesimal that the amount of metal passing into solution will not be sufficient to respond to chemical tests even after long periods.

Let us consider, in this light, the case of a piece of ordinary commercial iron in contact with the electrolyte water.

Such a piece of iron is impure and not homogeneous—there are some parts of it which have a different solution-pressure from other parts, and so when it is placed in contact with the electrolyte water we have all the conditions for the production of an electric current.

If the conditions are such that an appreciable electric current can pass between the two electrically different parts of the iron the metal will dissolve at the relatively electropositive parts. The fact that iron is practically insoluble in pure water (in the absence of oxygen) shows that the current which actually does pass is so infinitesimal that the amount of iron dissolved cannot be detected, even after long periods, by chemical means.

This may be due to two causes, namely, (a) the small magnitude of the electromotive force owing to the small differences of potential between the electrically different parts of the metal, and (b) the great resistance offered to the passage of an electric current by the electrolyte.

The writer's experiments⁷ seem to be generally accepted as proving beyond any doubt that commercial forms of iron will undergo corrosion quite readily in contact with pure water and pure oxygen in the complete absence of carbonic acid or any other acid—that the only essentials for the corrosion of ordinary iron are water and oxygen. It is generally believed that iron must pass through a process of solution before rust is produced, and so, while the metal is practically insoluble in pure water alone, it must be soluble in the presence of oxygen. It follows, then, that oxygen must bring about some alteration in the conditions of the "voltaic circle"—commercial iron and water—in such a way that a greatly increased electric current passes between the electrically different parts of the iron.

That oxygen can bring about such a change of conditions is beautifully illustrated by an experiment described by Dunstan and Hill.⁸ Cushman⁹ has shown that if a piece of commercial iron is left in contact with a solution of sodium chloride to which a little phenolphthalein has been added, a pink color develops in the solution which is in contact with some parts of the metal. These color zones, which are always confined to a portion (or portions) only of the metal, indicate the presence of hydroxyl ions (or free alkali) at these points. After being kept some time, the metal beneath the pink zones remains quite bright, but corrosion takes place gradually at the other parts of the metallic surface.

This experiment shows that the solution is being electrolyzed, and that the iron is passing into solution at those parts not marked out by the pink color of the phenolphthalein. It shows also that some parts of the iron are electrically different from other parts, and that the electromotive force produced by these differences of solution-pressure is enough, under these conditions, to cause the passage of an electric current of sufficient magnitude to produce perceptible electrolysis of the solution of sodium chloride.

It was shown by Dunstan and Hill, however, that the extent of this electrolysis was conditioned by the presence of oxygen, because, in the absence of air (or oxygen), the pink zones were not developed, and therefore an electric current sufficient to produce perceptible electrolysis could not pass.

Oxygen, therefore, must do one of two things—it must in some way or other increase the electrical differences between the parts of the metal and so increase the electromotive force,

or it must reduce the resistance of the circuit. When a piece of commercial iron is put into water in a vacuum, iron strives to pass into solution at the relatively electropositive part of the metallic surface, but hydrogen, produced by the electrolysis of the water, is deposited at the relatively electronegative part. This film of hydrogen, forming almost simultaneously and covering up the negative pole, introduces an enormous resistance into the circuit, and reduces the electric current to an almost negligible strength, so that the rate at which the iron passes into solution is infinitely small.

Oxygen dissolved in the water probably acts by deoxidizing the hydrogen deposited at the negative pole—destroying the polarization—and so allowing a greater current to pass between the electrically different parts of the metal.

If this argument is true, then commercial iron ought to pass into solution, in the absence of oxygen, if it is placed in an electrolyte, such as copper sulphate solution, where, instead of the non-conducting hydrogen film, there would be a conducting film of metallic copper produced at the relatively electronegative pole. Experiment shows this to be true. Commercial iron, when brought into contact with a solution of pure copper sulphate in a vacuum, causes the immediate deposition of copper on the iron just as readily as when the experiment is conducted in the presence of air; in a short time all the copper is removed from the solution and iron takes its place.

It seems to be clear then that when commercial iron rusts in contact with air and water, oxygen plays an important part in the actual dissolving of the iron, quite separate and distinct from its later function of converting the dissolved iron into rust.

The formation of rust from the dissolved iron is not, as it is sometimes supposed, a simple oxidation of the ferrous ions. It is not possible for the ferrous ion to be oxidized to the ferric ion by means of ordinary molecular oxygen. This can readily be proved by a simple experiment. If a solution of ferrous sulphate is made strongly acid with sulphuric acid and oxygen is passed through the solution, comparatively little ferric salt will be found in the solution even after the oxygen has been passed through it for several days. The greater the proportion of free sulphuric acid present, the less the oxidation which takes place. The oxygen only oxidizes the undissociated ferrous hydroxide formed by the hydrolysis of the ferrous salt, and since ferrous hydroxide is a very weak base, hydrolysis is very considerable unless a large excess of acid is present.

In the rusting of iron, then, the metal passes into solution as ferrous ions owing to electrolytic action between the electrically different parts of the iron, oxygen playing an essential part in the process. The ferrous ions then combine with the hydroxyl ions present in the water to form undissociated ferrous hydroxide:

At this stage oxygen plays a second part, converting the ferrous hydroxide into ferric hydroxide or some hydrated form of ferric oxide (rust).

The fact that iron rust produced under ordinary atmospheric conditions is shown, on analysis, to contain carbonic acid—that rust formed under such conditions is a basic carbonate of iron—does not necessarily prove, as has been supposed, that carbonic acid plays any essential part in its formation. Wet ferric hydroxide absorbs carbon dioxide, so that the carbonic acid found in rust formed under these circumstances may very probably have been absorbed from the air by the rust after its formation.

It follows from the theory that if we could produce metallic iron chemically and physically homogeneous it ought not to rust, because there would not be any differences of solution-pressure on its surface, and therefore no cause for the production of electric currents when the iron was placed in an electrolyte.

It would follow also from the theory that the production of a coherent and absolutely homogeneous coating, of whatever

nature, on the surface of commercial iron would prevent corrosion. The bearing of this on the question of passivity is discussed later.

The Properties of Chemically Pure Iron Considered in Connection with the Electrolytic Theory of Corrosion

The present writer¹⁰ has prepared chemically pure iron, and it has been found that such iron can be exposed to the action of air (or oxygen) and water (either distilled or tap-water) for an apparently indefinite time without showing any signs of corrosion. It must be strongly emphasized, however, that *chemical* purity is not the only essential.

In the preparation of pure iron by the writer's method the same sample of ferric nitrate, treated in exactly the same manner throughout its conversion into iron will not always give like specimens of the metal.

One batch of iron will rust quite readily, while another batch can be exposed for many months to the action of air and water without showing any signs of corrosion. All the pieces of the same batch behave, as a rule, in a precisely similar manner. Now any difference between the batches cannot be due to differences in *chemical* composition. The only possible variable factors are temperature of reduction and rate of cooling, and so differences in the product must be of a *physical* and not a *chemical* character.

It is a very striking fact that the pieces of iron which will not rust can also be put in solutions of copper sulphate or copper nitrate, of any strength, without causing copper to be deposited on the iron, while pieces from a batch of iron which rusts always cause the deposition of copper from the same solutions of copper salts. Sometimes the copper is deposited quickly, while at other times several hours may elapse before the deposition of copper takes place. The metal is always attacked at one or more points, and the deposition of copper spreads from these points over the whole surface in a very short time.

It is clear from these experiments that physical differences in iron of the same high state of chemical purity can cause most profound differences in its behavior.

If the theory is true, we should expect such results. In the case of the iron which does not rust and is unaffected by solutions of copper sulphate or copper nitrate, the metal is probably physically homogeneous, at any rate on the surface. There would, therefore, be no differences of solution-pressure (no electrically different parts) on the surface of the metal, and so no tendency for the metal to pass into solution by electrolytic action when the metal was put into an electrolyte. Since iron could not, therefore, pass into solution, we should not expect rusting to take place, nor should we expect the deposition of copper on the iron from solutions of copper salts.

The processes preceding corrosion and the deposition of copper from copper salt solutions upon metallic iron are undoubtedly similar in character.

In the case of the samples of pure iron which rust and which cause the deposition of copper from solutions of copper salts, the metal, although chemically pure, is not physically homogeneous, owing probably to some inequality in the temperature of reduction or the rate of cooling.

If such be the case, differences of solution-pressure would exist on the surface of the metal, and when it was put into an electrolyte there would be a tendency for electric currents to be set up between the electrically different points. In water, in the presence of air, this would lead to corrosion, in copper salt solutions to the deposition of copper. An interesting confirmation of such an argument is furnished by the following experiments.

Some pieces of the pure metal were taken which had been exposed to the action of water and air for several months without showing any signs of corrosion. They were carefully dried between pure Swedish filter paper, and then some of them were subjected to pressure in a polished agate mortar

¹⁰Trans. Chem. Soc., 1910, 97, 2430; 1912, 101, 2068.

by an agate pestle, while others were left untouched. Some of the pressed pieces were then put in distilled water and exposed to the air; they rusted in the course of a few hours, rust forming first at the edges which had not been pressed by actual contact with the agate, while the pressed portions remained quite bright. Others of the pressed pieces were put into a solution of copper sulphate; copper was deposited immediately on the metal, deposition first commencing at the unpressed edges of the pieces.

The pieces of iron which had been dried, but not pressed, neither rusted when placed in contact with water and air again, nor did they cause copper to be deposited from copper sulphate solution, so that it was the application of pressure alone which caused the profound alteration in the properties of the iron.

This again is readily explained by the theory. If a piece of iron be originally homogeneous and part of it be subjected to a strain, then the piece will consist of two parts, a strained and an unstrained part. It will contain two different modifications of iron, each having a different solution-pressure. If such a piece of iron be put in an electrolyte, there would now be a tendency for the passage of an electric current between the two electrically different parts, and so we should expect corrosion to take place when the iron was placed in contact with water and air. The fact that corrosion and the deposition begin at the unpressed part shows that this part is relatively electropositive to the pressed part.

These same points are illustrated in a striking and beautiful manner by the use of the ferroxyl reagent described by Cushman and Gardner.¹¹ The pure iron which does not rust is unaffected by the ferroxyl reagent, while the pure iron which is not physically homogeneous, or has been subjected to pressure, causes the development of the beautiful colors which indicate electrical differences, or differences of solution-pressure on the surface of the metal.
